Real Estate Equities – Real Estate or Equities?

Alexander Schätz
Statement of Purpose

The Working Paper series of the UniCredit & Universities Foundation is designed to disseminate and to provide a platform for discussion of either work of UniCredit economists and researchers or outside contributors (such as the UniCredit & Universities scholars and fellows) on topics which are of special interest to UniCredit. To ensure the high quality of their content, the contributions are subjected to an international refereeing process conducted by the Scientific Committee members of the Foundation. The opinions are strictly those of the authors and do in no way commit the Foundation and UniCredit Group.

Real Estate Equities – Real Estate or Equities?

Abstract

This study examines whether real estate stock indices in the United States and the United Kingdom are predominantly driven by the underlying property markets or by progress on general stock markets. In the process, we abandon the conventional approach of focusing on only the three assets, namely real estate equities, direct real estate and stock indices. Instead, we conduct an analysis which explicitly takes into account the macroeconomic environment in each country.

Based on vector error correction models (VECM) and variance decompositions, we detect a significantly stronger linkage among the real estate assets compared to the equity assets in the long run. However, despite these long-term similarities, we also identify differences concerning the linkage to the respective economic environment. Accordingly, we find a close nexus of the US real estate market with the real economy, while the financial market indices in the UK are predominantly focused on each other.

JEL Classification Codes: C32, G11, L85

Keywords: real estate investments, cointegration, vector error correction model (VECM), macroeconomics
1. Introduction

Real estate as an asset class describes a considerable investment vehicle for private, commercial and institutional investors. Primarily thanks to their nature as a real asset, investments in properties reveal different features compared to conventional assets like stocks and bonds. In particular, this applies to long-term investment horizons and is recognisable by low correlations and a distinctive risk/return structure, which in turn is accountable for being classified as an alternative asset. With respect to issues of asset allocation, investments in real estate therefore provide remarkable potential for diversifying an investor's portfolio.1 Earlier studies measuring the diversification benefits, such as Eichholtz (1996), Eichholtz et al. (1998), Liu and Mei (1998) or Liu et al. (1997), find favourable characteristics of real estate investments, including high stability of value, comparatively low volatilities and opportunities to hedge against inflation.

Investments in direct real estate nevertheless suffer from several disadvantages. Unlike stocks or bonds, neither the market volume nor the spectrum of the international real estate market has been developed to a sufficient extent up to now. In addition to issues of illiquidity, property investments are characterised by low information efficiency and insufficient market transparency. These drawbacks are noticeable in comparatively high information costs and thus increasing transaction costs, which in turn significantly reduce profit margins.

In the recent past, however, we have observed an ongoing expansion of securitised real estate.2 Investors are nowadays faced with a wide range of products related to real estate investments. Besides the conventional investment in direct real estate (residential or rental properties), investors also have opportunities to invest in several forms of securitised real estate, such as closed and open-end funds, listed real estate companies, REITs or real estate private equity. In this context, listed real estate in particular provides opportunities to adjust the disadvantages outlined above. Accordingly, the listing on stock exchanges ensures that prices are calculated in real time and favours transparency on markets for real estate investments in this way. In addition, the division into shares reduces the minimum investment amounts and, by implication, the market entrance barriers for potential investors. As a result, listed real estate provides an easier way for investors – in particular for private investors – to participate in the progress of the real estate sector.

A further consequence of listing on stock exchanges is that additional drivers – besides the development of the underlying properties – affect the performance and the risk/return structure of the

---

1 Generally, the term “property” is used in British English and “real estate” in American English, respectively. For the purposes of our examination, however, we use the term “property” in order to denote direct real estate investments, while the term “real estate” denotes real estate as an asset class in general, including securitised real estate.

2 According to Brounen et al. (2006) the market capitalisation for securitised real estate rose to USD 800 billion as of the end of 2005.
listed asset to a significant extent. Consequently, the asset’s performance is dependent on current economic news, which implies that the company value is not spared from the general stock market risk, including incorrect analyst expectations and valuations. As the equity price is subject to supply and demand, it might therefore suffer from irrational behaviour on stock markets, for example due to exaggerations in phases of boom and bust, or caused by the well-known herding behaviour of investors.³ As a result, listed companies are faced with the risk that market values are predominantly driven by developments on general stock markets, although the main business of real estate companies remains unchanged and is still focused on trading and renting real estate.

For this reason, it is worthwhile analysing whether real estate equities can still be characterised as real estate investments in their primary meaning and whether their distinctive features as an alternative investment still persist despite listing on stock exchanges. Previous studies, such as Liu and Mei (1992), Li and Wang (1995), Karolyi and Sanders (1998), Pagliari et al. (2005) and Hoesli and Serrano (2007), among others, examined this question and reached inconsistent results which are largely dependent on the selected method or the sample under consideration. Therefore, despite considerable research, there is still no incontrovertible evidence on this issue.

Macroeconomic System

According to Lizieri et al. (1998), real estate markets are generally considered to be cyclical in nature. Therefore, it is possible that the structure of market behaviour differs across phases of boom and bust. This might be recognisable by lower adjustment velocities after deviations from the equilibrium or by different volatilities of property values depending on the economic situation.⁴ For this reason, we presume a significant contribution of the macroeconomy to the explanation of developments on real estate markets in general and for analysing the features of real estate equities in particular.

Using a different approach, our study is focused exactly on this issue and examines whether real estate stock indices in the United States and the United Kingdom are primarily driven by the progress on property markets or by developments on general stock markets. Deviating from the conventional procedure of only focusing on the three financial market indices, namely real estate equities, direct real estate and general stocks, we conduct an analysis which explicitly takes into account the macroeconomic environment in each country. Following this approach allows us to consider the

³ In this context, several irrationalities on capital markets were detected by different studies within the research branch of behavioural finance. For example, the findings of Kahneman and Tversky (1979) contradict the basic tenets of utility theory. The authors detected a value function that is normally concave for gains, but commonly convex and generally steeper for losses. Furthermore, Shiller (1981) discussed the stock market’s efficiency and found that volatility of stock prices is much higher than fundamentally justified. For an overview concerning further possible irrationalities and their distinctions from current economic theory, please refer to Andrikopoulos (2007).

⁴ With regard to general stock markets, this issue was analysed by Black (1976), who found that falling prices are more volatile than rising prices.
effects resulting from interdependencies between the macroeconomy and the three asset classes mentioned above.

The remainder of this paper proceeds as follows. Section 2 reviews the related literature. Section 3 introduces the selected data and outlines the progress of the macroeconomic environment during the examination period. Section 4 presents the model framework. Section 5 provides empirical evidence and Section 6 concludes.
2. Literature Review

The scope of this examination covers a wide range of research branches. Besides the analysis of the distinctive features of real estate assets, it is also necessary to consider the literature on the impact of the macroeconomy on the real estate sector.

Nature of Real Estate Assets

The benefits of both direct and listed real estate with respect to diversification in a multi-asset portfolio have been discussed in various studies. Several authors certify favourable features of real estate investments in terms of geographical diversification in particular. In this context, real estate provides even more attractive advantages than international diversification through stocks and bonds. For example, Eichholtz (1996) detects significantly lower correlations between national real estate returns compared to common stocks or bond returns and therefore concludes that international diversification reduces the risks of a real estate portfolio to a larger extent than conventional asset portfolios. Case et al. (1997) find that geographical diversification within different types of commercial real estate, namely industrial, office and retail, is profitable. Furthermore, the study of Eichholtz et al. (1998) examines the impact of continental factors on real estate returns and verifies the existence of attractive international diversification potential for European and US investors. These favourable features of international real estate diversification are additionally confirmed by the studies by Newell and Webb (1996) and, with respect to industrial real estate, by Goetzmann and Wachter (2001).

Concerning the issue of whether real estate equities are dominated by properties or general stocks, previous studies reach inconsistent results which are largely dependent on the selected method, market or sample. In this context, related literature on integration characteristics of listed real estate is primarily focused on US markets using REIT data (see e.g. Liu and Mei, 1992, Karolyi and Sanders, 1998, and Ling et al., 2000). In the process, several studies detect high correlations of securitised real estate to common stocks. For instance, Li and Wang (1995) conduct a multifactor asset pricing (MAP) model and find that the US REIT market is integrated with the general stock market. Oppenheimer and Grissom (1998) use frequency space correlations and come to the same conclusion, according to which US REITs show significant co-movement with stock market indices. Moreover, by using regressions Quan and Titman (1999) detect significant relations between stock returns and changes in property values and rents in 17 different countries. This finding is additionally confirmed by the analysis of Ling and Naranjo (1999), who also examine whether commercial real estate markets are integrated with equity markets. Using multifactor asset pricing (MAP) models, the study finds that the risk premium of the market for exchange-traded real estate companies is integrated with the equity market. The authors additionally note that the degree of integration has significantly increased during the 1990s. In contrast, the integration hypothesis does not apply to real estate portfolios which are based on appraisal-based investments.
Another cluster of studies find that correlations between direct real estate and securitised real estate have increased over time (see e.g. Gosh et al. (1996) for the US market). Clayton and MacKinnon (2001) examine the sample between 1978 and 1998 for the US market by the use of a multi-factor approach. Although direct real estate does not contribute to the explanation of REIT returns over the entire sample, the study shows time-varying results concerning the link between REITs, direct real estate and financial assets. Nevertheless, they also find increasing correlations among direct and indirect real estate. Time-varying correlations are also detected by Hoesli and Serrano (2007), who analyse the relationships between securitised real estate, stocks, bonds and direct real estate in 16 economies. The international analysis reveals decreasing regression betas over time, indicating that the influence of the financial assets on securitised real estate has become less important in recent years. Nevertheless, the general stock market and bonds still explain a significant fraction of the variance of securitised real estate. As this does not apply to direct real estate, the results suggest that securitised real estate is driven by stocks and bonds rather than by their underlying property markets.

A third cluster of more recent studies, however, contradicts the results of the earlier studies outlined above and indicates that real estate securities behave more like properties than like general stocks in the long run (see e.g. Pagliari et al., 2005, Westerheide, 2006, Tsai et al., 2007, or Morawski et al., 2008). These findings point to opportunities for investors to combine the advantages of listed real estate with those of direct property investments and would have remarkable implications with respect to asset allocation in a multi-asset portfolio. As there is still no undisputed evidence concerning this question, neither provided by studies that address the pre-modern REIT era before the early 1990s nor by those that address the modern REIT era, we contribute to the literature by analysing this issue through a different approach. Accordingly, we assume that strict observation of econometric requirements as well as the consideration of the macroeconomic environment ensures reliable results.

**Real Estate and Macroeconomics**

A large body of literature analyses the linkage between the real estate sector and the general macroeconomy, although mainly focused on inflation. In this context, Hartzell et al. (1987) find that portfolios of commercial real estate hedge against both expected as well as unexpected inflation. Gyourko and Linneman (1988), however, distinguish between direct investments in non-residential property and REIT investments. While non-residential property investments are mostly positively correlated with inflation, REIT investments are similar to conventional equity or bond investments and thus strongly negatively correlated with inflation. Using regressions, limited opportunities were also detected by Liu et al. (1997) for the sample between 1980 and 1991. They found that real estate securities do not represent a better hedge against inflation than common stocks in the five examined countries.

In contrast, Quan and Titman (1999) and Hoesli et al. (2008) detect favourable features of real estate investments to hedge against inflation. Quan and Titman (1999) use regressions and attest that real
estate is positively driven by inflation as well as by the GDP. By employing a vector error correction (VEC) approach, Hoesli et al. (2008) examine the interactions between the economy, stock indices and public and private real estate between 1977 and 2003. Considering the impact of real and monetary variables, the authors find a positive long-run linkage between commercial real estate returns and anticipated inflation in the United States and the United Kingdom, while the converse holds for inflation shocks.

Further empirical studies have been conducted in order to identify the most important macroeconomic determinants for the progress of real estate indices. In this context, McCue and Kling (1994) use VAR models and find significant influences of the factors of inflation and three-month treasury bills on US REIT returns. Ensuing variance decompositions indicate that nearly 60% of the variation in real estate prices is explained by the macroeconomy and that it is the nominal short-term interest rate that explains the majority of the variation in real estate series. More studies, such as those by Liang et al. (1995) or Mueller and Pauley (1995), focus on the linkage between real estate prices and interest rates by assuming that this linkage is time-varying and differs depending on periods of high and low interest rates. Using a threshold autoregressive (TAR) model for the real estate markets in the United States and the United Kingdom, Lizieri et al. (1998) distinguish between two interest rate regimes. In general, their results clarify that decreases in real estate prices are more extreme in a high real interest environment than the increases associated with lower real rates.

In their study on the risk/return structure of publicly-traded real estate companies, Bond et al. (2003) find that the consideration of country-specific market and value risk factors in particular provide additional explanatory power, although this finding is not universally valid over all 14 countries under consideration. Therefore, the authors conclude that the potential of international diversification with real estate companies cannot reliably be assessed without having regard to the standards for regulation and disclosure as well as governance standards of the related companies. According to Bond et al. (2003), the results of Hamelink and Hoesli (2004) point to a dominance of the country factor over property-type factors. A further highly significant role is also detected for the value/growth factor, which is characterised by substantial levels of volatility.

Using multifactor asset pricing (MAP) models, Sing (2004) examines the effects of systematic market risk factors and common risk factors on the variations in excess returns of securitised and direct real estate investments. For this purpose, the author uses the SUR estimation technique and the standard Fama and MacBeth (1973) two-pass regression technique to estimate the risk premiums in the proposed MAP models. The evaluation of the test results shows that macroeconomic risk factors are priced notably differently in securitised and direct real estate markets. In contrast, Wang (2006) follows another approach, whereby he uses the functional relationships between real estate returns and economic activities in the UK to infer the extent to which an appraisal-based index is
smoothed. Using this method enables the correction of appraisal-smoothing and the detection of the true market volatility information.
3. Data Selection

Real Estate and Stock Market Data

With respect to regulation, disclosure and accounting standards, we still find remarkable differences across international real estate markets.\(^5\) As these country-specific distinctions significantly influence results, reduce comparability and therefore affect inferences, using a reliable and consistent data set is particularly important for the purposes of our examination.

Real estate markets in the United States and the United Kingdom are characterised by high transparency and low transaction costs compared to other real estate markets in industrialised countries. Furthermore, the market for US and UK property companies is much more actively traded than other national real estate markets, and in this way highlights the higher level of development and liquidity. As a consequence of this, real estate markets in the US and the UK supply reliable data and representative indices for both direct as well as indirect real estate investments, which is vital to our approach of analysing the features of real estate equities. Admittedly, this does not apply to further national real estate markets, as the according direct property indices in particular are not comparable to the well-known and widely-used US NCREIF and the UK IPD or do not cover the required period.\(^6\)

The NCREIF Property Index (NPI), provided by the National Council of Real Estate Investment Fiduciaries, has been published since 1978 and currently covers 5,976 US properties – including all types of real estate – and presents a market value of USD 328 billion (as of 2008:q1). The UK counterpart is represented by the property index of the Investment Property Database (IPD), which incorporates monthly adjustments or appraisals of the underlying properties and contains 3,695 properties with a market value of £40.8 billion as of August 2008 (Investment Property Database (IPD), 2008).

In the US model we also use the FTSE NAREIT Equity REIT Index of the National Association of Real Estate Investment Trusts (NAREIT) as a proxy for the American real estate stock market. This index is a sub-index of the FTSE NAREIT US Real Estate Index series and only includes companies which own or operate income-producing real estate, such as apartments, shopping centres, offices, hotels and warehouses. Currently, this index contains 110 constituents with a net market capitalisation of USD 276.638 million (as of January 2008). In the UK model we use the capitalisation-weighted UK FTSE 350 Real Estate Index to cover the British real estate sector.

In order to cover the influences of the general stock market, we use the respective benchmark indices for the US and UK equity markets. As frequently done in previous studies, the general stock market is

\(^5\) For a discussion see Bond et al. (2003).

\(^6\) In this context, it would also be interested to analyse transaction-based real estate indices. Due to our approach of evaluating the vector error correction models in detail, we prefer to focus only on NPI and IPD.
represented by the FTSE 100 Index in the UK model, while the S&P 500 Composite Index is used to cover the general stock market in the United States. Due to the fact that US REITs are largely contained in the S&P Small Cap 600 Index, another possibility could be to use this subindex for the purposes of this examination.7

However, we prefer not to use the Small Cap 600 Index, as any measure of dependence between REITs and this subindex could – by construction – be upward biased.8

Macroeconomic Data
The selection of the macroeconomic factors is based on theoretical assumptions and represents a good compromise between covering the most important influences resulting from the economic environment without over-parametrising the models. The determinants are represented by the consumer price index (CPI) as a proxy for inflation, the real gross domestic product (GDP) as a proxy for economic growth and the interbank rates (three months) for considering the influences of the money market. Interbank rates represent a major indicator for the resulting credit costs and in this way primarily cover aspects of bank lending. As interbank rates can furthermore be taken as an indicator for the aggregate investment climate of an economy, we prefer the use of this time series to long-term interest or mortgage rates.

The implemented approach allows the analysis of possible inflation-hedging characteristics of investments in real estate. According to economic theory, real estate is largely classified as a hedging instrument against inflation, because owners benefit from increasing nominal income and capital growth, while the real value of their debt is eroded (Lizieri et al., 1998). Furthermore, due to the characteristic as a real asset, the net asset value of the related property is not subject to depreciation of money to such an extent as conventional assets like equities or bonds. Furthermore, particularly with respect to commercial properties, rental contracts largely contain inflation subscripted rental payments. In this way, the adverse effects of rising inflation can be compensated to a significant extent. Nevertheless, our results clarify that passing a blanket judgement is pointless in this context. Instead, considering the complete business environment and its interrelationship to the real estate sector is indispensable for each country under consideration.

Testing for Structural Breaks
In order to preclude misinterpretation and consequently incorrect economic implications due to instability in the deterministic trend, we examine the dataset for structural breaks. Taking into account

---

7 As of June 2009, the portfolio weighting of US REITs only amounts to 5.8% of the S&P Small Cap 600 Index. Source: Morningstar Database.
8 Furthermore, following this approach does not improve validity, because the index history is not as long as that of the S&P 500 Composite Index.
structural breaks is particularly important when applying cointegration techniques. Ignoring the existence of structural breaks leads to unreliable unit root test decisions and consequently to the risk of misspecified estimation models (Perron, 1989). As illustrated in Figure 3-1, the periods at the beginning of the 1990s, after the collapse of the New Economy in 2000 and around “9/11” in 2001 are particularly worth testing, because the recessions and their consequences for credit markets ought to be closely linked to our real estate-related macroeconomic model.

We prefer to apply stability tests on the basis of dynamic multivariate models if employing cointegration techniques. In so doing, we abandon the approach of the related studies, which primarily use CUSUM and CUSUMQ tests or Chow tests on the basis of OLS regressions. As the stability hypothesis is rejected far too often for multivariate dynamic models with many parameters relative to the number of available observations, we use the bootstrap versions of the Chow test according to Candelon and Lütkepohl (2001).9 We examined the data from 1978:q1 to 2008:q2 for the US model and from 1988:q1 to 2008:q2 for the UK model for structural breaks. The splitting sample Chow tests are applied on the basis of VEC models.10

In both economies, the results of the tests for structural breaks divide the sample in 1992:q1 (see Figures 7.1 and 7.2 in the Appendix). As a result, the examination period is set from 1992:q1 to 2008:q2 for both economies and therefore allows for comparisons of the results between both national economies.

---
9 For further details see Candelon and Lütkepohl (2001).
10 The date for the structural break is verified using different VECM orders in order to minimise the impact of individual model specifications. Nevertheless, these alternative specifications are in line with the evaluation principles as outlined below. As all test orders indicate structural breaks at the end of 1991 or at the beginning of 1992, we start our sample in 1992:q1.
datasets. Although data is available from 1978:q1 to 2008:q2 for the US model and from 1988:q1 to 2008:q2 for the UK model, we prefer to examine the sample after the detected structural breaks, because the estimation results for the whole sample are not sufficiently robust compared starting the analysis as of 1992. This lack of robustness is recognisable by the fact that significance and signs of coefficients vary depending on our manual specifications, namely the selection of the model order or the implemented restrictions within the cointegrating vectors. In this context, neither recursive estimations nor moving windows provide evidence of robust results. In short, covering the whole sample would lead to instable results and most likely to unreliable economic implications.11

Covering the sample after the detected structural breaks, however, ensures robust results even if individual model specifications are changed.12 Accordingly, even though we accept to cover, at least approximately, one real estate cycle, following this approach ensures econometrically correct results and allows reliable economic implications. Moreover, the identified date of the structural breaks can reasonably be explained by the recessions that occurred at that time and their tremendous consequences for credit markets. Subsequent to the saving and loan crisis during the late 1980s, the US recession began in July 1990 and was worsened by a credit crunch in the US financial sector. In addition, modifications in tax legislation led to remarkable changes in the structure of US real estate markets (Glascock et al., 2000). Accordingly, the anticipation of the consequences due to the Omnibus Budget Reconciliation Act in 1993 resulted in a remarkable increase in the underlying equity capital of REITs and thus in a historical shift in US real estate investment markets.

In the UK, however, a boom in the housing market during the 1980s and the consequential increases in house prices stimulated consumer spending, which in turn resulted in remarkable increases in the rate of inflation. Consequently, the Bank of England increased interest rates to as high as 15% in 1989:q4 in order to protect the value of the British pound (see Figure 3-2). The costs of mortgage payments increased and led to a rising number of home repossessions and falling house prices. As a consequence of this, consumer spending decreased and caused an economic slowdown which ultimately resulted in the 1991 UK recession.

Nevertheless, the recovery in both countries was supported by a remarkable decrease in the key interest rates of the corresponding central banks (see Figure 3-2). While the US federal funds rate

11 In this context, another possibility would be to artificially extend the sample by applying techniques to repair the structural breaks. Nevertheless, the implementation of dummy variables has neither in the intercept nor in the long-term or short-term dynamics produced any convincing or stable results. The corresponding results are available on request.

12 Where alternative model specifications are chosen only the magnitude of coefficients vary, whereas significance and signs of coefficients remain largely unchanged.
amounted to 9.75% in 1989:q1, the ongoing expansive monetary policy ended at the 3% level at the end of 1993. The same applies to the monetary policy of the Bank of England. The reduction of interest rates began at the 15% level at the end of 1990 and ended at 5.25% at the beginning of 1994.

**Descriptive Statistics**

Table 3-1 outlines all time series used and presents the corresponding descriptive statistics for their first differences. A comparison between both economies reveals several similarities and we therefore assume a comparable economic environment during the examination period in the two economies under consideration.

Due to their nature as interest rates we observe that the interbank rates show comparatively high standard deviations. In addition to equal algebraic signs of the means, the CPI, the GDP and the general stock market display comparable values in both economies. As the investigation period after the recessions is congruent with a long-term upward trend in the real estate sector, we furthermore find comparatively high mean values of the direct and indirect real estate indices in each country.

---

13 In addition, immense currency speculation imposed pressure upon the British pound during that time. In particular, this applies to September 16, 1992, the date which came to be known as the “Black Wednesday”. Despite considerable intervention measures by the Bank of England (BoE), the deterioration of the UK currency could not be stopped and ultimately resulted in the UK opting out of the European Exchange Rate Mechanism (ERM).

4. Methodology

Cointegration and VECM

For the purposes of this examination we conduct a cointegration framework and the Johansen (1988) procedure.\textsuperscript{14} The concept of cointegration is traced back to Granger (1981, 1986) and Engle and Granger (1987). It combines time series analytical procedures with the concept of economic equilibrium, and facilitates the analysis of long-term equilibrium relationships between non-stationary variables. The cointegration analysis is based on the observation that economic variables often display common trend behaviour. This implies that linear combinations of these variables converge towards a common equilibrium in the long term, even though individual time series fluctuate over time. According to Engle and Granger (1987), time series are cointegrated if they display the same degree of integration and a linear combination of these variables is stationary. Furthermore, the use of the time series in their levels guarantees that information losses due to the conventional use of first differences are avoided. According to the Granger representation theorem, the dynamic adjustment process of cointegrated variables towards the long-term equilibrium path can be represented by an error correction model (ECM). In this way, long-term equilibrium relationships are combined with short-term dynamics.

Deviating from the existing studies concerning the features of securitised real estate, we additionally take into account the case of multi-dimensional cointegrating relationships. Consequently, the evaluation of the implemented VEC models is not limited to the long-term relationships in the β-vectors. Instead, the adjustment process (α-vectors) and cross-vectoral effects are also considered. By following the approach of taking into account the economic environment within the scope of vector error correction models, it is possible to examine the relevant channels which are responsible for the adjustment process after deviations from the long-term equilibrium.

By considering the periods after the structural breaks, the PP tests indicate that the examined time series are non-stationary in their level specification and stationary in the first differences (see Table 7-1 and 7-2 in the Appendix). Consequently, all variables display the same degree of integration.\textsuperscript{15} The cointegration analysis can therefore be conducted on the basis of a consistent dataset.

\textsuperscript{14} As several papers contribute to the development of the Johansen procedure as it is used within the scope of this study, the denoted year refers to the first paper of the VECM series by Johansen and Juselius.
\textsuperscript{15} Due to the more precisely formulated hypotheses, we prefer the results of the Phillips-Perron (PP) test (Phillips, 1987, and Phillips and Perron, 1988) to those of the augmented Dickey-Fuller (ADF) test (Dickey and Fuller, 1979, 1981) in case of deviating results. By virtue of the correction procedure according to Newey West (1994) as well as the Bartlett window, the PP test provides robust results both in the case of present autocorrelation and for time-independent heteroscedasticity (Perron, 1989).
In order to detect the existence of cointegrating relationships, we employ the trace test and the maximum eigenvalue test. Determination of rank and estimation of the coefficients are performed as a maximum likelihood estimation. The corresponding likelihood-ratio test statistics are:\(^1^6\)

\[ \lambda_{\text{Trace}} = -T \sum_{r=1}^{k} \ln(1 - \lambda_r) \]  
\[ \lambda_{\text{Max}} = -T \ln(1 - \lambda) \]  

\(\lambda\) represents the estimated eigenvalues of the reduced rank of matrix \(\pi\). In the process, the sequential test strategy begins with \(r = 0\) and is continued until the null hypothesis for the 5% significance level cannot be rejected for the first time. The related value of \(r\) ultimately corresponds to the cointegration rank. In this way there are \((n-r)\) stochastic trends in the system. In this study the corresponding critical values are used in accordance with Osterwald-Lenum (1992). The applied cointegration tests display the existence of three cointegrating relationships within the VAR model for the US economy and two for the UK counterpart.

Modelling of the non-stationary variables as a vector autoregressive (VAR) process \(Y_t\) of finite order \(k\) forms the basis of the Johansen (1988) procedure. If at least two of the variables are cointegrated of the order of one, then the VAR\((k)\) process can be reparametrised and written as a vector error correction model:

\[ \Delta Y_t = \mu + \pi Y_{t-1} + \sum_{i=1}^{k-1} \Gamma_i \Delta Y_{t-i} + \varepsilon_t \]  

\(\Delta Y_t\) is a \((n \times 1)\) vector of the first differences of stochastic variables \(Y_t\) and \(\mu\) is a \((n \times 1)\) vector of the constants. The lagged variables are contained in vector \(Y_{t-1}\). The \((n \times n)\) matrices \(\Gamma_i\) represent the short-term dynamic. The coefficients of the cointegrating relationships (cointegration vectors) and of the error correction term are contained in the matrix \(\pi\). \(\pi\) can be decomposed as follows:

\[ \pi = \alpha \beta' \]  

\(^{16}\) The choice of the underlying lag structure of the VAR models is based in the first stage on the information criteria of Akaike (AIC), Schwarz (SC) and Hannan-Quinn (HQ). We furthermore test the models for heteroscedasticity and autocorrelation. Should both or either occur in the consequential VEC models we choose the next highest order. In all models examined the use of this approach enables misinterpretation of the test results to be avoided at the tolerable expense of losing a few degrees of freedom. Prior to this decision, it was necessary to conduct further analyses in order to preclude the possibility, that other reasons such as high values of correlation among the selected variables, are responsible for the significant deviations from the null hypothesis of the White (1980) test.
ß represents a \((n \times r)\) matrix of the \(r\) cointegrating vectors. The \((n \times r)\) matrix \(\alpha\) contains the so-called loading parameter, i.e. those coefficients that describe the contribution of the \(r\) long-term relationships in the individual equations. Here \(\alpha\) and \(\beta\) have full rank. It should be noted that the analysis of \(\pi\) is not definite. If in Equation (4-3) \(\pi\) is replaced by the Equation (4-4), then the error correction representation follows (vector error correction model, VECM):

\[
\Delta Y_t = \mu + \sum_{i=1}^{k-1} \Gamma_i \Delta Y_{t-i} + \alpha' \beta Y_{t-1} + \varepsilon_t \tag{4-5}
\]

**Variance Decomposition**

Employing variance decompositions provide further information on the relative significance of the individual variables in explaining index development. To do this, the variance of the errors discovered ex post is allocated proportionately to the examined variables. As this method is also conducted on the basis of vector error correction models, we once more take into account the dynamic character of the interrelations among the considered variables. By determining the Cholesky order, a causal structure is implicitly assumed among the variables of the system. This is expressed in the distribution of the common components of the interference terms in favour of the variables preceded in the Cholesky order. This fact could have a major influence on the results, especially in the case of a strong correlation between the original error values. As a consequence of this, we verify the results of the variance decompositions as outlined in the Appendix (Table 7-3 and 7-4) by choosing alternative Cholesky orders. Although the absolute values fluctuate slightly, the results are robust and the rank order among variables remains unchanged.
5. Empirical Results

Prior to the analysis of the features of real estate equities, we evaluate the implemented model framework with respect to econometric requirements and economic plausibility. In this way we are able to assess the features of real estate equities on the basis of reliable test results.

Despite the well-known disadvantage of vector error correction models, namely their sensitivity, both implemented models meet the econometric requirements which have been defined prior to the estimation. In addition, the signs of the macroeconomic factors can reasonably be explained by economic theory. As a result, this VECM framework, including the implemented model specifications, is adapted for examining and evaluating the features of real estate equities.17

The VECM results for the examination period between March 1992 and June 2008 are summarised in Tables 5-1 and 5-2. Based on the cointegration test results we find three cointegrating relationships in the US and two cointegrating relationships in the UK model. In each model, the first and second ü-vectors are normalised to the direct and securitised real estate index, respectively, while the third one in the US model is normalised to the CPI index.

The implemented restrictions are accepted by the LR tests. Furthermore, the p-values of the White tests consistently indicate that the risk of heteroscedasticity is eliminated.18 Both VEC models are additionally tested for stationarity by the Dickey-Fuller (DF) test using the critical values according to Banerjee et al. (1993). Although not significant in every case, the adjustment coefficients for the error correction terms display negative signs, indicating a return to the long-term equilibrium path. Due to the decomposition of the τ matrix, the use of the error correction approach allows the evaluation of long-run relationships as well as the adjustment mechanism separately (see Equation 4.4). Accordingly, the vectors for the long-term relationships are outlined in Table 5-1 and the vectors with reference to the adjustment processes are displayed in Table 5-2.

Significance and Signs

We find consistent signs of the macroeconomic variables in both examined economies which also apply to economic theory. As expected, the real estate assets are positively affected by the general

17 Within the scope of this examination we choose equal evaluation principles in order to allow for comparisons between both countries. These principles require that the normalised variable significantly contributes to the long-term equilibrium in the respective vector. In this context, the case of multidimensional cointegrating relationships is explicitly taken into account. For this purpose, we apply hypotheses tests in order to verify whether individual coefficients can be restricted to zero without accepting significant losses of information. In so doing, only a single regressor is eliminated in each step. The identification of those individual factors which significantly contribute to explaining the country-specific equilibrium is based on the results of the tests for linear restrictions (LR tests). If individual variables do not significantly contribute to the detected equilibrium, these factors are restricted to zero within the corresponding vector. In this case information is only provided via the coefficients related to the adjustment process.

18 The estimated models are free of possible hazards caused by autocorrelation occuring within the residuals, too, although this is not explicitly mentioned in Table 5-1.
stock markets, while negative effects are detected due to an increase in the interbank rates in each economy.

For the purposes of our examination, the interbank rates are used as an indicator for the interest rate levels, which are ultimately decisive for the resulting credit costs. Referred to individual projects, returns on properties and developments suffer from increasing interest rates and the resulting adverse effects on project-specific debt financing. As investments in properties in particular are known to require a high ratio of debt capital, the increase in the interbank rates leads to a further decreased demand for property investments, which in turn results in decreasing property prices. However, the positive sign of the interbank rates (in the third vector of the US model) also applies to economic theory, as in that case the vector is normalised to the consumer price index. In this context, our results confirm the findings of Geltner et al. (2007), who classify the money market as the best hedge against inflation on the condition that the investor reinvests in the money market. Moreover, our results indicate a negative relationship between the CPI and the GDP, which once more clarifies the adverse long-term effect of rising inflation on domestic economic growth.

Nevertheless, the inter-country comparison reveals a difference in terms of possible inflation-hedging characteristics of real estate assets. According to the US model, a positive relationship is detected
between the consumer price index and the NAREIT (vector 2 and 3), indicating that investments in real estate equities benefited from rising inflation during the examination period. In contrast, this does not apply to real estate investments in the UK, as the estimations do not indicate significant coefficients – neither positive nor negative – of the CPI variable in either vector. These distinctions are in line with the inconsistent findings of the related studies outlined above. Therefore, our results affirm that conclusions on the issue of whether real estate represents an appropriate tool to hedge against inflation cannot reliably be drawn without considering the complete business environment and its interrelationship to the relevant real estate sector.

**Linkage to the Macroeconomy**

With regard to the cointegrating relationships in their entirety, our results consistently feature distinctions between the markets in the United States and the United Kingdom. While we find a stronger linkage to the macroeconomic environment in the United States, the financial market indices in the United Kingdom are predominantly focused on each other. This distinction is recognisable by both the long-term relations and the observed adjustment processes.

In the US model, the macroeconomic determinants CPI and GDP significantly contribute to the explanation of the long-term equilibrium in the US model (see Table 5-1). The third vector is primarily focused on the real economy, indicating that the long-term equilibrium is determined by the CPI, the GDP, the interbank rates and the real estate equity index. In contrast, neither of these aspects applies to the UK model, where the real economy – represented by the GDP and the CPI – does not significantly contribute to the long-term equilibria.

In addition to the long-term relations (β-vectors), we take into account the results of the adjustment processes (α-vectors) and the corresponding cointegration graphs. The α-vectors describe the adjustment process when the linear combinations deviate from the long-term equilibrium path. In that case, the α-vectors indicate in which way this disequilibrium affects the remaining model variables (see Table 5-2). The corresponding cointegration graphs for the observed paths are illustrated in Figure 7-3 in the Appendix.

The evaluation of the α-vectors affirms the outlined differences concerning the long-term relationships (β-vectors) in both examined economies. As a consequence, the mode of the adjustment process back to the long-term equilibrium is remarkably different in the US economy compared to the UK. Accordingly, deviations from the long-term equilibrium affect neither the real estate assets nor the general stock market in the US model. Instead, these disequilibria significantly affect the GDP, the consumer prices and the interbank rates. This mode of adjustment can therefore be interpreted as a remarkable orientation towards the US macroeconomy. In contrast, this does not apply to the UK model, where disequilibria affect the general stock index (in both vectors) and the property index.
very significantly and therefore indicate a remarkable orientation towards the financial market indices.

Notes: Bold type denotes significant results based on t-statistics (in parentheses). All values are first differences. For reasons of clarity we omit the corresponding constant c and the error term ε. NCREIF = direct property index in the US, NAREIT = real estate equity index in the US, IPD = direct property index in the UK, REE = FTSE 350 Real Estate Index as a proxy for the real estate equity market in the UK, CPI = domestic consumer price index, INTER = interbank rates (3 months), GDP = real gross domestic product, SP500 = Standard & Poor’s 500 Stock Index, representing the general stock market in the US, FTSE = FTSE 100 Index, representing the general stock market in the UK.

The reason for these outlined distinctions between both economies can reasonably be explained by the interdependency among economic growth, credits and inflation. In principle, the sample from 1992:q1 to 2008:q2 is characterised by increasing demand for properties and increasing property prices in both real estate markets. Contemporaneously, this progress was enhanced by comparatively high GDP rates relative to low interbank rates. During that period of time, the GDP rates only revealed one remarkable decline due to the aftermath of the “9/11” terrorist attacks in 2001, even though still indicating positive rates of economic growth. Despite the comparatively resistant economic growth, the interbank rates in both economies even feature negative mean values over the examination sample, and in this way additionally stimulated loan-financed investments.19 As a consequence, this instance particularly facilitates investments in properties which largely rely on a high ratio of debt capital and therefore benefit from decreasing credit costs by nature.

As this ratio has been even more extreme in the US economy over the whole sample period, this instance results on the one hand in additional demand for loan-financed investments in the United States. On the other hand, in accordance with economic theory, the functional chain of economic

---

19 Compared to the key interest rates of the corresponding central banks, the interbank rates reveal a spread as a risk premium for lending money to competitors. Nevertheless, the interbank rates are known to be largely influenced by these key interest rates. For this reason, the outlined effects are closely linked with the expansive monetary policy of the US Federal Reserve during the examination sample. However, examining the effects of monetary policy and the strategies on how to intervene in the money market is not the subject of the current paper, but of another one.
growth, low levels of interest and increasing property prices imply rising rates of inflation. This fact can easily be identified by the significant contribution of the CPI variable within the US VEC model (see Tables 5-1 and 5-2). Moreover, this finding is additionally affirmed by larger US CPI mean values over the examination sample compared to the UK counterpart (see Table 3-1). As in this context inflationary expectations also increase by implication, loan-financed investments are also stimulated in terms of inflation, because real indebtedness decreases over time on the basis of rising inflation.

As a result, via the channel of a more extreme ratio of high GDP rates relative to low interest rates and its consequential stimulating effects on real estate and inflation, this process results in self-intensifying effects and in this way affects the real economy and real estate markets as well. For this reason, the US economy is ultimately closer linked with its real estate sector than the economy in the UK, where this ratio has been slightly more moderate and in the end did not trigger self-intensifying effects.

Features of Real Estate Equities

As mentioned above, due to the fact that both implemented models meet the econometric requirements and the macroeconomic influences can furthermore be reasonably explained by economic theory, we use the outlined VECM framework in order to analyse the features of real estate equities.

The real estate equity indices in both economies are significantly influenced by the progress on the underlying property markets. The model estimations show a strong linkage between the real estate equity indices and the direct properties, indicating that both real estate assets affect each other positively in the long run. This strong linkage is recognisable by their unalterable contribution to the long-term equilibrium (in vectors one and two in each model) with comparably high t-values. Restrictions of one of these two real estate assets are rejected by the LR test and would lead to significant losses of information within both VEC models. Moreover, this finding is robust if choosing alternative VEC specifications.\(^{20}\)

In each economy, one cointegrating vector is determined by the examined financial market indices (vector 1 in the US model and vector 2 in the UK model). Independent of the implemented normalisation, the corresponding direct property index, the real estate equity index and the general stock market significantly contribute to the long-term equilibrium in these vectors, indicating equal signs in both countries. Therefore, both the property index and the general stock index significantly determine the progress of the real estate equity index.

In order to analyse whether real estate equities primarily reflect real estate or equities, some studies take the comparison of the corresponding coefficients as a basis for their decision. The fact that the

\(^{20}\) Although choosing alternative VEC specifications, we nevertheless keep the evaluation principles as outlined above.
general stock market is only included in one vector in each model, while both real estate assets significantly contribute to the long-term equilibrium in at least two vectors, describes a further widely-used but not quite reliable criterion in this context. With respect to the outlined VECM results, both aspects would suggest a closer linkage between the real estate assets compared to the equity assets and would therefore indicate that the distinctive features of real estate investments still persist despite the listing on stock exchanges. Nevertheless, we prefer to employ further analyses and therefore conduct additional variance decompositions in order to verify the VECM results and to gain further insights into this issue.

Variance Decomposition

As indicated in Figure 5-1, a comparatively substantial contribution to the variance of the US NAREIT is explained by the NCREIF (46.53%), while the S&P 500 only explains a significantly smaller fraction (13.43%). This implies that the real estate equity index in the US is driven more by its underlying property market than by the general stock market. For this reason, we can take this result as a stronger linkage among the real estate assets than the equity assets.

![Figure 5-1 Variance Decompositions.](image)

**Notes:** NCREIF = direct property index in the United States, NAREIT = real estate equity index in the United States, IPD = direct property index in the United Kingdom, REEI = FTSE 350 Real Estate Index as a proxy for the real estate equity market in the United Kingdom, CPI = domestic consumer-price index, INTER = interbank rates (3 months), GDP = real gross domestic product, SP500 = Standard & Poor’s 500 Stock Index, representing the general stock market in the US, FTSE = FTSE 100 Index, representing the general stock market in the UK.

Although not indicating comparable values, the same applies to the UK. The real estate equity index is primarily influenced by the GDP (23.88%), while the IPD and the FTSE Composite Index explain

---

21 The denoted values refer to the numerical output in Appendix 7.4.
14.25% and 9.85%, respectively. In addition, we find in both economies a remarkable growth in influence of the property indices when considering longer periods. In contrast, the reverse applies to the impact of the general stock markets, as its measured contribution is characterised by a tendency to decline over time.

For this reason, the results of the implemented variance decompositions consistently indicate a closer linkage among the real estate assets compared to the equity assets in both economies. The long-term synchronicity between listed and direct real estate consequently implies that the distinctive features of real estate investments in their primary meaning still persist despite the influences of the general stock market.

Accordingly, in spite of being subject to supply and demand, the developments of the underlying real estate properties remained the key driver of the performance of listed real estate during the examined sample. As a result, besides benefits in terms of liquidity, transparency and management, long-term investments in listed real estate offer opportunities to combine advantages of both direct and listed real estate, and therefore also provide remarkable potential for diversifying the investor’s portfolio.
6. Conclusions

Investments in listed real estate imply that the progress on the underlying property markets no longer represents the only driver of the performance and risk/return structure of this asset. Instead, listed companies are faced with the risk that market values are predominantly driven by developments on general stock markets, although the main business of the constituents remains unchanged and is still focused on trading and renting real estate properties. For that reason, it is worthwhile considering to what extent developments on general stock markets influence the progress of listed real estate. Answering this question is of particular importance with respect to issues of asset allocation in a multi-asset portfolio. If predominantly driven by progress on general stock markets, the benefits of listed real estate in terms of portfolio diversification would be considerably limited. By implication, the intended risk/return structure of an investor’s portfolio would be significantly distorted, because the consideration of listed real estate would involuntarily increase the proportion of investments that are subject to general stock market risk. Consequently, this scenario would ultimately result in a portfolio allocation which is riskier than requested.

For that reason, our study is focused on the issue of whether real estate stock indices are primarily driven by the progress of property markets or by developments on general stock markets. For the purposes of this examination, we analyse the real estate markets in the United States and the United Kingdom in the period since 1992. Deviating from the conventional procedure of exclusively focusing on the three financial market indices, namely real estate equities, direct real estate and general stocks, we follow the approach of taking into account the macroeconomic environment in each country. As real estate markets are considered to be cyclical in nature, the consideration of the macroeconomy avoids the ignoring of information resulting from the business environment and thus the impact of the cyclical trend.

Using a vector error correction framework and variance decompositions, in both economies we consistently find a significantly stronger linkage among real estate assets compared to the linkage among the examined equity assets. The real estate equity markets are therefore predominantly driven by the progress of the underlying properties, which can therefore still be interpreted as the key driver of listed real estate in the long run. Long-term investments in listed real estate therefore not only provide opportunities for portfolio diversification, but additionally allow the combination of advantages of both real estate assets, including benefits in terms of liquidity, transparency and management. As a result, investments in real estate equities can still be classified as an alternative investment and therefore still represent a favourable tool in terms of asset allocation.
In addition to examining the features of real estate equities, the approach of taking into account the economic environment for the purposes of this study allows comparisons with respect to the relevance of the real economy in the examined real estate markets. In this context, the inter-country comparison reveals one striking distinction according to which the progress of the real estate sector in the United States is more closely linked to the macroeconomy than is the case in the United Kingdom. This distinction is recognisable by both the determination of the long-term relationships and during the observed adjustment process in case of disequilibria. In contrast, we do not detect comparable linkages in the British economy, where the financial market indices predominantly stimulate each other.

In this context, we identify the ratio of GDP and interest rates as the principal reason for the closer linkage to the macroeconomy in the United States. Throughout the whole examination sample, we find higher GDP rates relative to lower interest rate levels in the US economy, which was responsible for additional demand for loan-financed investments and in this way further increased property prices. Accordingly, via this channel and its consequential stimulating effects on inflation, the economic environment in the United States is more severely affected by these developments, which ultimately results in the closer nexus with its real estate sector.

This study clarifies that long-term investments in real estate equity indices still fulfill their function as an alternative investment in order to diversify an investor’s portfolio. For that reason, we further on assume lower correlations to conventional assets and a more defensive risk/return structure compared to investments in general stocks. Nevertheless, if considering shorter investment horizons, passing a blanket judgment is pointless in this context, despite the consistent long-term results. Instead, considering the distinctive features of the respective real estate sector and its linkage to the complete business environment is indispensable in order to be able to assess influences on real estate equity indices in the right way.

Notes: Here, the zero line represents the long-term equilibrium and the curve shows the deviations. In principle, the evaluation of the cointegration graphs reveals similarities between both real estate markets. According to the graphs, deviations from the long-term equilibrium range between a comparable order of magnitude in the cointegrating relations 1 and 2. Limited to the period between 1992 and 1993, relation 1 of the UK model displays the only exception in this context. The main distinction, however, is represented by the existence of a third cointegrating relationship within the US model which is furthermore primarily focused on the real economy. As indicated by the low scale values of this cointegrating relationship, deviations are kept within bounds and were quickly absorbed by the macroeconomy during the examination sample.
Variance Decomposition
