**Statement of Purpose**

The Working Paper series of the UniCredit Foundation is designed to disseminate and to provide a platform for discussion of either work of the UniCredit economists and researchers or outside contributors (such as the UniCredit Foundation scholars and fellows) on topics which are of special interest to the UniCredit Group. To ensure the high quality of their content, the contributions are subjected to an international refereeing process conducted by the Scientific Committee members of the Foundation.

The opinions are strictly those of the authors and do in no way commit the Foundation and UniCredit Group.

**Scientific Committee**

Marco Pagano (Chairman), Klaus Adam, Silvia Giannini, Tullio Jappelli, Eliana La Ferrara, Christian Laux, Catherine Lubochinsky, Massimo Motta, Giovanna Nicodano, Branko Urosevic.

These Working Papers often represent preliminary work. Citation and use of such a paper should take account of its provisional character.

**Editorial Board**

ABSTRACT

I examine the asset pricing implications of technological innovations that allow capital to displace labor: automation. I develop a theory in which firms with high share of displaceable labor are negatively exposed to such technology shocks. In the model, firms optimally adopt technology to gain competitive advantage in the product market. Although automation increases an individual firm’s competitive advantage, in equilibrium competition erodes profits and decreases firm value. Empirically, I develop a firm-level measure of displaceable labor share, based on detailed job classifications from the O*NET database, and find that firms with high displaceable labor share have negative exposure to technology shocks. A long-short portfolio sorted on this new measure is highly correlated with existing macroeconomic measures of technology shocks. Firms with negative exposure to these technology shocks earn a 4% per year return premium. The premium is positively predicted by decreases in the cost of capital goods. At the firm level, I confirm that a large negative exposure to technology shocks predicts lower employment and profitability following technology shocks, and these effects are amplified by higher within-industry competition.

JEL classification: G12, J24, O33.

* I am very thankful to my committee members, Adlai J. Fisher, Lorenzo Garlappi, Jan Bena, Murray Carlson, and Jesse Perla for their guidance and support. I thank Carolin Pflueger, Markus Baldauf, Ilan Cooper, Jack Favilukis, Boyan Jovanovic (discussant), Leonid Kogan, Yang Liu (discussant), Ding Luo (discussant), Joseba Martinez (discussant), Dimitris Papanikolaou, Lawrence Schmidt (discussant), Zhongzhi Song, Harald Uhlig, seminar participants at the University of Rochester, the University of California at San Diego, the University of Washington, University of Oxford, the University of Amsterdam, BI Norwegian Business School, Stockholm School of Economics/Swedish House of Finance and conference participants at the Adam Smith Junior Workshop 2019 (LBS), CFEA 2019 (NYU Stern), ESSEC Nonstandard Investment Choice Workshop 2019, NFA 2019, CICF 2019, the Belgrade Young Economists Conference 2019 (University of Belgrade), IRMC 2019 (Bocconi), Yale Doctoral Fall Finance Conference 2018, the Macro Financial Modeling Summer Session at the Becker Friedman Institute 2018, UBC Finance Summer Conference 2018 and FMA Doctoral Consortium 2018 for valuable comments. All remaining errors are my own.

Saïd Business School, University of Oxford, Park End Street, OX1 1HP, Oxford, UK, jiri.knesl@sbs.ox.ac.uk
Technological advances over the last four decades have led to adoption of many new technologies. An important subset of these innovations, including for example robots and software, focus on automation that displaces human labor in favor of machine capital (see, e.g., Acemoglu and Restrepo (2017) and Autor, Levy, and Murnane (2003)). The massive adoption of such technologies by businesses, the associated large-scale displacement of routine-task labor, and the resulting society-wide impacts have been termed “The Second Machine Age” (Brynjolfsson and McAfee, 2014). The importance of this wave of automation for the economy naturally raises the question of how automation has affected, and continues to affect, asset prices.

In this paper, I study whether firms’ share of displaceable labor that can be automated by capital affects firms’ value and their exposure to technology shocks. The amount of routine tasks which can be automated varies across occupations and thereby across industries. I find that firms with high share of displaceable labor have more negative exposure to technology shocks that facilitate automation. I demonstrate that a long-short portfolio of firms sorted on their share of displaceable labor replicates the dynamics of price changes in capital goods, thus creating a strong connection between a macroeconomic variable and the dynamics of stock returns. I further show that firms with a negative exposure to technology shocks earn an average return premium of 4% per year. The premium varies over time, being high in periods of strong technological progress, and is positively predicted by decreases in prices of capital goods. These properties of the premium are consistent with a compensation for households’ time-varying job displacement risk arising from technological progress.

To understand these findings, I develop a general equilibrium model of optimal technology adoption with heterogeneous firms that compete in product markets, and heterogeneous households that experience uninsurable idiosyncratic labor-income shocks. In the model, all firms within a given industry have the same opportunity to adopt technology. I show that a technology shock that facilitates automation decreases profits and market value of firms that can replace labor by capital. Although additional economic mechanism such as market entry, operating leverage or inability of firms to adopt new technology can strengthen this result, this model points out that only a realistic assumption of product market competition is necessary to obtain this outcome. The model further highlights that the price of risk of technology shocks depends on households’ idiosyncratic labor income when some of the households are replaced by capital.

In the model, a technology shock embodied in capital allows firms to use cheaper capital-based, instead of labor-based, production. Automation, which creates an optimal displacement of labor by capital, leads to a lower production cost but entails technology adoption cost. In a competitive environment, a firm’s profit depends on its product price relative to the product prices of its competitors. This gives rise to a strategic element in a firm’s decision to adopt technology. As all firms in a given industry have the same share of displaceable labor, a symmetric Nash equilibrium of optimal automation exists. Because automation lowers a firm’s product price relative to its

---

2See Autor and Dorn (2013). This paper provides similar results.
competitors and increases its revenues, upon the occurrence of a technology shock each firm in
the industry has an incentive to automate despite the technology adoption cost. These benefits
deteriorate as the number of automated firms in the industry increases and lower product prices
become the industry-wide standard. As a consequence, automation does not provide an advantage
but is rather a costly necessity to stay competitive. I show that in equilibrium, technology shocks
lead to lower profits and firm value. Firms with a displaceable labor share have negative exposure
to such technology shocks.

An appealing feature of the model is its flexibility to generate both positive and negative
price of technology shocks. The sign of the price of risk depends on the dispersion of individual
workers’ future labor productivity. Technology shocks create risk for households. The adoption of
capital-based production reallocates workers from old to new occupations. Although on average
all workers will be more productive in their new occupations, individual workers experience either
increase or decrease in their productivity. This labor productivity shocks are purely idiosyncratic
and realized only once the worker moves to the new occupation. Since the occurrence of these
idosyncratic shocks is triggered by the aggregate technology shocks and markets are incomplete,
the idiosyncratic risk affects the premium of the aggregate technology shock. If the dispersion of
the individual labor productivity shocks is low, households do not fear technology shocks that facilitate
automation and the technology shocks generate good states for all households. If the dispersion of
individual workers’ productivity increases, households dislike technology shocks as some of them
may lose parts of their labor income. This result highlights the importance of imperfect risk sharing
as described in Constantinides and Duffie (1996) and its relationship to technological progress as
described in Kogan, Papanikolaou, and Stoffman (2017), and Gárleanu and Panageas (2017).

Empirically, I measure a firm’s share of displaceable labor by a ratio of labor that can be
easily substituted by capital and the firm’s current capital stock. To construct this measure, I
classify employees’ occupations by the routine intensity of their tasks using a comprehensive set of
occupational characteristics from the O*NET database and merge the occupational level data with
firm data for employment and capital stock from Compustat. I find that the share of displaceable
labor is predominantly an industry-level characteristic. The variation between industries explains
70% of the total cross-sectional variation in the share of displaceable labor.

I use changes in quality-adjusted relative prices of capital goods as an empirical measure of tech-
nology shocks The theoretical foundation of this measure has been shown in previous literature
(e.g., Cummins and Violante (2002); Hornstein and Krusell (1996)) and is based on the idea that
improvements in the production of capital goods such as machines and software are reflected in
lower prices of these goods adjusted for changes in quality. I empirically verify this assumption using
data from the NBER-CES Manufacturing Industries database and the Input-Output Accounts

3O*NET database is currently the primary source of occupational information in the U.S. It provides a comprehen-
sive and updated set of occupational characteristics such as required skills and abilities or importance of various
activities and tasks. O*NET database is administered by the U.S. Department of Labor/Employment and Training
Administration through the O*NET Resource Center. The predecessor of the O*NET database is the Dictionary of
Occupational Titles whose data are incorporated in the first releases of the O*NET database.

from the U.S. Bureau of Economic Analysis (BEA). Decreases in quality-adjusted prices of capital goods are indeed associated with improvements in industries producing capital goods.

I first show that portfolios of firms sorted on their share of displaceable labor have large differences in their exposure to technology shocks. Firms with the highest share of displaceable labor have strongly negative exposure to technology shocks. The magnitude of the exposure decreases monotonically across the portfolios toward firms with low share of displaceable labor. A long-short portfolio based on this measure successfully approximates the time-series of technology shocks with a correlation of 0.6 and a strong overlap in all periods of large technology shocks. This result is present among both manufacturing and non-manufacturing firms. I show that the differences in the risk exposure to technology shocks are also not driven by firms’ differential exposure to other risk factors.

Second, I investigate whether firms’ risk exposure to technology shocks earns a return premium in the cross section of stocks. I first show that technology shocks measured by the changes in quality adjusted relative prices of capital are a state variable indicating the risk of labor income for households. Assets that co-move with this state variable are expected to earn a premium. I find that firms with strongly negative exposure earn a return premium of 4% per year. The average returns monotonically decrease across portfolios toward firms with weak risk exposure. Firms’ size or growth opportunities might be related to firms’ share of displaceable labor and correlate with the stock returns in the cross section. I first show that the Capital Asset Pricing Model (CAPM) and the size (SMB) and value (HML) factors do not explain the return premium. I next show that standard cross-sectional return predictors do not explain the return premium in firm-level panel regressions. I use conditional double sorts and show that the premium is also not driven by these return predictors in a non-linear way.

Third, I investigate the time variation and predictability of the return premium. If the estimated return premium is associated with labor-income risk, it will follow a similar pattern over time. The labor-income risk is high in states of high technology shocks when the prices of capital goods decrease. I find that the return premium is predictable by the changes in the prices of capital goods. Periods of positive technology shocks, which decrease the prices of capital goods, are associated with high return premium. In a companion paper (Knesl, 2018), I show that decreases in the prices of capital goods increase households’ labor-income risk and job-displacement risk as cheaper and more productive capital substitutes for human labor. This evidence further rationalizes the return premium for technology shocks as a compensation of labor-income risk.

Last, I examine whether firms with different exposure to technology shocks differ also in their behavior upon the occurrence of technology shock. Firm’s differential behavior and financial performance following technology shocks provide a valuable indication for the underlying economic mechanism. I find that when the relative prices of capital goods decrease, firms with strongly negative exposure decrease employment and increase capital more than firms with weak exposure.

---

5NBER-CES Manufacturing Industries database from Becker, Gray, and Marvakov (2013) provides data on productivity and other variables at a detailed industry level. The Input-Output Accounts from the BEA provide MAKE and USE tables that allow to categorize industries into industries producing capital and consumption goods.
These firms also experience large decrease in sales, return on capital and return on equity. This evi-
dence directly supports the conjecture that firms’ risk exposure to technology shocks reflects firms’
financial underperformance associated with changes in production technology following a technol-
gy shock. I document that these effects are stronger for firms in highly competitive industries, a
finding that underlines the importance of product market competition.

Two important ideas how technology shocks can decrease value of existing firms have been
described in previous literature. Greenwood and Jovanovic (1999); Hobijn and Jovanovic (2001)
show that the inability of incumbents to adopt new technology that arrived at the beginning of
1970s is behind the drop in stock values of existing firms during following decade. Pástor and
Veronesi (2009) shift the focus to learning about the profitability of a new technology. They show
that learning and technology adoption change the originally idiosyncratic risk of a new technology
into systematic, which creates a bubble-like pattern with a stock price decrease towards its end. In
this paper, I take a different route and focus on the strategic element of technology adoption. The
value of firms in my model decreases as firms strategically adopt costly technology but eventually
compete away the potential rents. The papers above are primarily concerned with the effect of
technology shocks on aggregate stock market and draw comparison mostly between incumbents
and new tech stocks. My focus is on technology shocks and the joint dynamics of cross-section of
stock returns and their investment and employment. The main dimension in the cross-section is
firms’ automation potential, defined as a share of labor that can be displaced by capital, where
existing firms with high automation potential are affected by technology shocks the most.

My paper is related to Papanikolaou (2011), who uses directly stock prices as a proxy measure
for technology shocks embodied in capital goods. Using a two-sector general equilibrium model, he
shows that relative stock prices of producers of capital goods are informative about capital-embodied
technology shocks. I take a different approach and develop a theory, where stock returns of different
(actual vs. potential) users of capital are informative about capital-embodied technology shocks.
Applying this approach to the U.S. data reveals a strong co-movement between stock prices of
firms with displaceable labor and relative prices of capital goods that has not been documented in
previous studies. A long-short portfolio constructed along the dimension of displaceable labor share
closely resembles the time series of technology shocks embodied in capital. Hence, this approach
complements the methodology in Papanikolaou’s paper.

A small but growing literature explores economic mechanisms how capital-embodied technol-
gy shocks affect firms’ expected returns (e.g., Papanikolaou (2011); Garleanu, Panageas, and Yu
(2012); Garlappi and Song (2017); Kogan et al. (2017)). The evidence of a substantial risk pre-
mium for capital-embodied technology shocks provided in this paper is valuable for two reasons.
First, it is based on an empirical measure whose dynamics closely resembles the dynamics of a
traditional macroeconomic low frequency measure of technology shocks. Second, the time-series
properties of the premium are consistent with time-varying properties of idiosyncratic labor-income
risk, which suggests an appealing mechanism of pricing technology shocks. The implications of
uninsurable idiosyncratic labor-income risk have been addressed in several prominent studies (e.g.,
Recent papers examine the effects of technological growth in the presence of imperfect risk sharing (e.g., Gärleanu, Kogan, and Panageas (2012); Gärleanu and Panageas (2017)). Consistent with these papers, my study adopts the promising feature of imperfect risk sharing in the theoretical model and provides empirical evidence of a return premium that can arise in such environment.

The aspects of this study described in the previous three paragraphs connect two streams of literature. A number of studies have examined the importance of technology shocks embodied in capital for economic growth (e.g., Greenwood et al. (1997); Kogan and Papanikolaou (2014)). This literature emphasizes that capital-embodied technology shocks increase the efficiency of capital investment and thereby stimulate investment in growth opportunities. I am also interested in technology shocks embodied in capital but primarily to understand their impact on labor. This relates my work to a second line of research that focuses on the ability of new types of capital to carry out tasks that used to be performed by human workers. For example, Autor, Katz, and Kearney (2006); Autor and Dorn (2013) link the large shifts in labor force across occupations and the employment and wage polarization to the spread of technology, e.g., computers, that can substitute human workers. Acemoglu and Restrepo (2018) analyze conditions under which automation and creation of new labor tasks establish a balanced growth path. My paper shows that technology shocks embodied in capital affect firms not only through their capital investment in growth opportunities as shown before, but also through their ability to substitute for labor in performing tasks, where it is technically feasible. Hence, these technology shocks are important for labor-intensive firms with a high share of displaceable labor. To the best of my knowledge, this study is first to draw the link between capital-embodied technology shocks and stock returns of these firms.

In a recent paper, Zhang (2018) analyzes how a firm’s displaceable labor relative to industry average affects firm’s market beta. Abstracting from technology shocks and prices of capital, he shows that firm’s displaceable labor relative to industry average lowers firm’s exposure to the aggregate stock market risk. Our studies differ and, in fact, complement each other in multiple ways. First, the emphasis of my paper centers on the importance of technology shocks and prices of capital for firms with displaceable labor, which is reflected in a co-movement between prices of these stocks and technology shocks embodied in capital. This co-movement arises primarily due to differences in firms’ displaceable labor share between industries, which is the primary source of variation in my variable. The variation of this variable within industries does not relate firms to technology shocks much. Hence, it seems appropriate to abstract from the forces of technology shocks in Zhang’s framework. They are, however, central in my analysis. While his paper is concerned with and provides important evidence for firm’s exposure to the aggregate market risk, my interest lies in the interplay between technology shocks, firms’ adoption of technology in competitive environment and the joint effects on firms and households. This gives rise to a new source of risk, which carries a time-varying return premium independent from the aggregate market risk.

The rest of the paper is organized as follows. In the next section, I develop a general equilibrium
model of an optimal adoption of technology that highlights how automation affects stock prices. 

Section II provides the data sources, construction and validity of the measures of displaceable labor share and technology shocks. I examine the exposure to technology shocks of firms with different share of displaceable labor in section III. Here, I also describe the zero-cost portfolio that approximates the empirical measure of technology shocks. Section IV documents the cross-sectional return premium and examines its properties including time-series predictability. This section also shows that firms’ exposure to technology shocks is associated with differential investment and employment policies and financial performance following technology shocks. I conclude in section V.

I. The Model

I develop a two-period general equilibrium model that provides a clear picture of how technology shocks affect asset prices through stimulating labor displacement and technology adoption. The model consists of two sectors with firms competing in monopolistic fashion and households supplying sector-specific labor. Technology shocks decrease the price of capital and motivate firms to automate by adopting capital-based production. The model is qualitative in its nature. This, however, allows me to embed the strategic element of technology adoption in a general equilibrium setting and focus on its implications for asset prices. The model shows firms’ optimal decision to adopt the capital-based production and its effects on the composition and risk exposure of firms within a given sector as well as the effect on the income of households supplying labor to the sector.

A. Firms, Technology, and Automation

The economy exists for two periods. The production side of the economy consists of two sectors $s \in \{1, 2\}$. Sector $s = 1$ initially consists of labor-based firms and sector $s = 2$ of capital-based firms. Firms in sector $s = 1$ have an opportunity to automate by adopting capital-based production upon the occurrence of a technology shock in the second period as described in more detail below.

Within each sector $s$, there are $N$ firms that produce firm-specific differentiated goods $Y_{f,s,t}$ at time $t$ and compete in monopolistic fashion. The number of firms is large enough so that each firm can abstract from the consequences of its choices for the sector level aggregates. Firms produce their goods using either a labor-based, $Y^l_{f,s,t} = L_{f,s,t}$, or a capital-based linear production function, $Y^k_{f,s,t} = K_{f,s,t}$. A firm with capital-based production buys sector-specific capital $K_{f,s,t}$ at price $P^l_{s,t}$. I assume that firm’s capital is active and fully depreciates in the period of investment.\(^6\) The cash

---

\(^6\)This assumption implies that firms cannot trade capital among themselves. Capital reallocation and spread of new technology through mergers and acquisitions has been studied by Jovanovic and Rousseau (2002, 2008) and reallocation of used capital by Esfahani and Rampini (2006, 2007). Trade in capital between firms across sectors can be optimal in a scenario when labor-based firms would benefit from acquiring capital from capital-based firms. I assume that capital is sector-specific so that firms cannot trade capital across sectors even if it doesn’t fully depreciate. I thank Boyan Jovanovic for pointing out this mechanism.
flow of a capital-based firm is

\[ CF_{f,s,t}^k = P_{f,s,t}^k Y_{f,s,t}^k - P_{s,t}^l K_{f,s,t}, \]

(1)

where \( P_{f,s,t}^k \) denotes the price of firm-specific good produced in a capital-based production. A firm with labor-based production hires sector-specific labor \( L_{f,s,t} \) at sector-specific wage \( W_{s,t} \). Labor-based firms have an option to automate by adopting capital-based production and paying automation cost \( \kappa \). Firms will optimally do so when the price of capital investment \( P_{s,t}^l \) becomes low enough. The cash flow of a firm with labor-based production is

\[
\begin{align*}
CF_{f,s,t}^l &= P_{f,s,t}^l Y_{f,s,t}^l - W_{s,t} L_{f,s,t} \\
CF_{f,s,t}^k &= P_{f,s,t}^k Y_{f,s,t}^k - P_{s,t}^l K_{f,s,t} - \kappa
\end{align*}
\]

(2)

where \( P_{f,s,t}^l \) and \( P_{f,s,t}^k \) are the prices of the firm-specific good.

Sector-specific capital, \( K_{s,t} \), is produced completely competitively in a linear production function with an aggregate technology level \( A_t \) and sector-specific labor \( L_{k,s,t} \) that is employed in production of capital.\(^7\)

\[ K_{s,t} = A_t L_{k,s,t} \]  

(3)

I further assume that installation of capital is subject to decreasing returns to scale at the total amount of sector-specific capital as described in equation\(^8\). The assumption of strictly decreasing returns to scale \( 0 < \alpha < 1 \) is important for the existence of a mixed-strategy equilibrium described below, but not for the final implications for stock returns\(^8\)

\[ I_{s,t} = K_{s,t}^\alpha \]  

where \( I_{s,t} = \sum_{f=1}^{N} K_{f,s,t} \)

(4)

Hence capital production and installation imply that individual firms face the following price of capital:

\[ P_{s,t}^l = \frac{1}{A_t} W_{s,t} I_{s,t}^{\frac{1}{1-\alpha}} \cdot \frac{1}{\alpha}. \]

(5)

Equation\(^5\) shows that an increase in technology \( A_t \) decreases the effective price of capital investment. This effect is partially offset by higher sector-level investment if \( \alpha < 1 \). The technology \( A_t \) and the total amount of sector-specific investment determine the marginal cost of capital-based production relative to the marginal cost of labor-based production. Automation becomes favor-

---

\(^7\)The assumption of perfect competition among capital producers does not allow the mechanism studied in Panikolaou (2011), where stock prices of capital goods producers are informative about technology shocks. This is not possible in this model as capital producers do not retain any rent. Although in real world capital goods producers retain some market power, this assumption is useful as it shows that the economic mechanism in this model described later is independent.

\(^8\)The assumption of decreasing returns to scale for installation of capital at the sector level implies that individual firms do not internalize the effect of their capital investment on the marginal cost of capital investment. It further implies that the amount of capital used in a sector is always equal or greater than the sum of capital investments of individual firms. This assumption is equivalent to adjustment or installation cost of capital at the sector level.
able when the marginal cost of capital-based production decreases relative to the marginal cost of labor-based production.

In the first period, sector \( s = 1 \) consists of firms that use labor-based production and have the option to automate. Sector \( s = 2 \) consists entirely of firms that already use capital-based production. The level of technology \( A_t \) is subject to a technology shock that is realized at the beginning of the second period. A technology shock increases the level of technology \( A_t \). Specifically, I assume an initial level of technology \( A^{Low} \) that can increase to \( A^{High} \) with probability \( p_H \) as described in (6):

\[
A_1 = A^{Low}, \quad A_2 = \begin{cases} 
A^{Low}, & \text{with probability } 1 - p_H \\
A^{High}, & \text{with probability } p_H 
\end{cases}
\]  

(6)

A technology shock \( A^{Low} \to A^{High} \) decreases the price of capital investment \( P^{I}_{s,t} \) in both sectors \( s = 1, 2 \). Allowing only a positive technology shock in the model is not restrictive. The model can be easily extended to allow for a negative technology shock. The assumption of constant or improving technology in this model implies constant or decreasing prices of capital investment. This is generally consistent with empirical evidence as the quality adjusted relative prices of capital goods experienced a secular decrease over the last four decades (see, Fisher (2006); Cummins and Violante (2002)).

The firm-specific goods are combined to sector-specific goods using a constant elasticity of substitution (CES) function:

\[
Y_{s,t} = \left( \sum_{f=1}^{2} Y_{f,s,t}^{\nu^{-1}} \right)^{\frac{\nu}{\nu - 1}},
\]  

(7)

where \( \nu \) is the elasticity of substitution between the firm-specific goods. I assume \( \nu > 1 \) which implies that the firm-specific goods are imperfect substitutes to each other. The prices of the sector-specific goods can be expressed as

\[
P_{s,t} = \left( \sum_{f=1}^{N} P_{f,s,t}^{1 - \nu} \right)^{\frac{1}{1 - \nu}}.
\]  

(8)

The sector goods are combined to an aggregate final consumption good using a CES function with a different elasticity of substitution, \( \rho \):

\[
Y_{C,t} = \left( \sum_{s=1}^{2} Y_{s,t}^{\rho^{-1}} \right)^{\frac{\rho}{\rho - 1}}.
\]  

(9)

I choose the aggregate consumption goods as a numeraire by setting its price \( P_{C,t} \equiv 1 \), and assume

---

9I document an average decrease in quality adjusted relative prices of capital goods of 4 percent per year since 1960 (see table A.10).

10An equivalent aggregation can be achieved when the sector-specific goods are consumed directly by households with CES preferences and elasticity of substitution \( \rho \).
that $\frac{\nu - 1}{\nu} > \frac{\rho - 1}{\rho}$. This assumption implies that firm-specific goods within a given sector are closer substitutes than sector-specific goods. For example, individual products in food industry substitute each other more readily than all food products substitute products of a different industry such as paper mills.

Firms within each sector compete in a monopolistic fashion. Given the production type, firms maximize dividends by setting the price of their goods:

$$D_{f,s,t}^l = \max_{P_{f,s,t}^l} \left\{ P_{f,s,t}^l Y_{f,s,t}^l - W_{s,t} L_{f,s,t} \right\} \text{ where } Y_{f,s,t}^l = \left( \frac{P_{f,s,t}^l}{P_{s,t}} \right)^{-\nu} Y_{s,t}$$

(10)

$$D_{f,s,t}^k = \max_{P_{f,s,t}^k} \left\{ P_{f,s,t}^k K_{f,s,t} - P_{s,t}^k K_{f,s,t} \right\} \text{ where } Y_{f,s,t}^k = \left( \frac{P_{f,s,t}^k}{P_{s,t}} \right)^{-\nu} Y_{s,t},$$

(11)

where $Y_{f,s,t}^l$ and $Y_{f,s,t}^k$ are the demand functions for the firms’ goods. The first order conditions of firms’ optimization in (10) and (11) imply that firms charge constant mark-ups over the marginal production cost:

$$P_{f,s,t}^l = \frac{\nu}{\nu - 1} W_{s,t} \text{ and } P_{f,s,t}^k = \frac{\nu}{\nu - 1} P_{s,t}^l.$$

(12)

Upon the realization of the technology shocks at the beginning of $t = 2$, firms in the labor-based sector $s = 1$ decide whether to automate the production. Automation changes the labor-based production to capital-based production by incurring automation cost $\kappa$:

$$D_{f,1,2} = \max \{D_{f,1,2}^l, D_{f,1,2}^k - \kappa\}$$

(13)

The fact that all firms in sector $s = 1$ are originally labor-based and operate in a symmetric monopolistic competition implies that all firms within this sector have equal incentive and opportunity to automate.11 This setup focuses on the within-industry competition and between-industry differences in firms’ automation potential. The empirical analysis in later sections shows that these two characteristics play an important role in firms’ exposure to technology shocks.

Automation changes the firm composition as well as the use of labor within the sector $s = 1$. $\delta = \frac{\sum_{f=1}^{N} \mathbb{1}_{\{Automate = Yes\}}}{N}$ denotes the percentage of firms in sector $s = 1$ that decide to automate. Automation shifts labor from the direct production of firms’ goods to the production of the sector-specific capital. $L_{1,2}^l = \sum_{f=1}^{N} L_{f,1,2}\mathbb{1}_{\{Automate = No\}}$ is sector 1’s labor that is employed directly in labor-based firms. $L_{1,2}^k = \frac{1}{\lambda_2} \left( \sum_{f=1}^{N} K_{f,1,2}\mathbb{1}_{\{Automate = Yes\}} \right)^{\frac{1}{2}}$ is sector 1’s labor that is employed in the production of the sector-specific capital. The total amount of labor in sector $s = 1$ is $L_{1,2} = L_{1,2}^l + L_{1,2}^k$.

11The motivation behind this setup is that, for example, car makers such as Ford Motor Company and General Motors Company have generally same automation potential. The automation potential of car makers is, however, different from the automation potential of, for example, internet companies such as Yahoo! and Google (part of Alphabet Inc.). At the same time, internet companies again resemble each other.
B. Households

There is a large number, $N_h$, of ex-ante identical households. Each household consists of two spouses, each of which supplies labor effort to a different sector. Households derive utility from consumption $c_{h,t}$ and disutility from labor effort $H_{h,1,t}$ and $H_{h,2,t}$ according to a utility function in the spirit of Greenwood, Hercowitz, and Huffman (1988):

$$U(c_h, H_{h,1}, H_{h,2}) = E \left[ \sum_{\tau=t}^{2} \beta^{\tau-t} \left( c_{h,\tau} - \chi H_{h,1,\tau}^{1+\theta} - \chi H_{h,2,\tau}^{1+\theta} \right) 1 - \gamma \right],$$

(14)

where $\beta$ is households’ subjective discount factor, $\chi$ governs the disutility of labor effort, $\gamma$ is the coefficient of risk aversion, and $\frac{1}{\theta}$ is the Frisch elasticity of labor supply. Assuming households with two spouses greatly simplifies the model solution as all households have, through their two spouses, exactly the same exposure to labor-income risks in each sector. This approach allows to easily embed idiosyncratic labor-income risk.

Now I introduce an idiosyncratic labor productivity risk. The labor effort $H_{h,s,t}$ transforms to $L_{h,s,t} = H_{h,s,t}$ effective hours of labor unless the spouse shifts from working directly in a labor-based firm to working in the production of sector-specific capital. If the spouse has to move to the production of sector-specific capital, the labor effort transforms to $L_{h,1,2} = (1 + \tilde{\epsilon}_h) H_{h,1,2}$ effective hours of labor. $\tilde{\epsilon}_h$ is the spouse’s idiosyncratic random variable that determines their labor productivity when they move to the new job. This shock can be interpreted as a permanent shock to individual human capital. The job movements are purely intra-sectoral. When firms in sector $s = 1$ automate by adopting capital-based production, a corresponding number of spouses will be displaced from these firms and employed in the production of sector-specific capital within the same sector $s = 1$. The spouses cannot observe their idiosyncratic labor productivity $\tilde{\epsilon}_h$ until they are employed in the new job. I specify the distribution of the idiosyncratic labor productivity by:

$$\tilde{\epsilon}_h = \begin{cases} 
-\epsilon & \text{with probability } p_{\epsilon} \\
+\epsilon & \text{with probability } 1 - p_{\epsilon} 
\end{cases} \text{ where } \epsilon > 0. \tag{15}$$

Markets are incomplete in the sense that households cannot trade an asset that would fully insure them against the realization of the idiosyncratic labor productivity. This framework of households and their income is analogous to Constantinides and Duffie (1996). Individual households are ex-ante representative, but exhibit ex-post heterogeneity in form of uninsurable permanent labor-income shock.

I deliberately choose the idiosyncratic labor productivity shock in form of mean preserving spread for multiple reasons. Mean preserving spread keeps the sector’s supply of effective hours of labor independent from the idiosyncratic labor productivity shocks. The possible realizations of...

---

12 Assuming purely intra-sectoral labor reallocation is not essential for the economic mechanism in this model.
positive values of $\epsilon_h$ reflect the idea that technology shocks create also better job opportunities. This is widely consistent with the literature documenting and explaining the polarization of the U.S. labor market (e.g., Autor et al. (2003); Autor and Dorn (2013)). The use of symmetric risk allows to focus only on the effect on households’ utility from possible dispersion of this shock similar to Constantinides and Duffie (1996)

To maximize their utility, each household solves following problem:

$$\max_{c_{h,t},H_{h,1,t},H_{h,2,t}} U (c_{h,t},H_{h,1,t},H_{h,2,t}) \text{ s.t. } c_{h,t} = D_{h,t} + L_{h,1,t} W_{1,t} + L_{h,2,t} W_{2,t},$$

where $D_{h,t} = \frac{1}{N_h} \left( \sum_{f=1}^{N} D_{f,1,t} + \sum_{f=1}^{N} D_{f,2,t} \right)$ is the households capital income. The specific form of the utility function ensures that households do not take the wealth effect of the idiosyncratic labor productivity shock $\tilde{\epsilon}_h$ into account when they decide the optimal labor supply. The first order condition determines the optimal labor effort as:

$$H_{h,s,t} = \left( \frac{W_{s,t}}{\chi} \right)^{\frac{1}{\theta}} s \in \{1, 2\}. \quad (17)$$

The total supply of labor to sector $s$ at time $t$ is $L_{s,t} = \sum_{h=1}^{N_h} L_{h,s,t}$. The symmetry of the distribution of $\tilde{\epsilon}_h$ ensures that the labor effort of spouses working in capital production in sector $s = 1$ at $t = 2$ is transformed to effective hours on average in the same way as the labor effort of spouses working directly in labor-based firms in the same sector, $E[L_{h,1,2}] = E[(1 + \tilde{\epsilon}_h) H_{h,1,2}] = H_{h,1,2}$.

The utility optimization gives a household-specific stochastic discount factor of the form:

$$\Lambda_h = \beta \left( \frac{c_{h,2}}{c_{h,1}} - \frac{H_{h,1,1}^{1+\theta}}{H_{h,1,2}^{1+\theta}} - \frac{H_{h,2,1}^{1+\theta}}{H_{h,2,2}^{1+\theta}} \right)^{-\gamma}, \quad (18)$$

Since all households are identical ex ante, the stochastic discount factors are identical across all households. Each single household prices assets in the same way. At the same time, aggregate consumption and labor efforts are not sufficient statistics for pricing firms as they omit the idiosyncratic component of households consumption due to the realization of the idiosyncratic labor productivity shock.

C. Valuation

The value of firms in labor-based sector $s = 1$ at $t = 1$ is given by:

$$V_{f,s,1}^l = D_{f,s,1}^l + E[\Lambda_h D_{f,s,2}], \quad (19)$$

---

This is a conservative approach, since the focus will be on a negative risk premium for the aggregate technology shock. Negatively skewed distribution of $\epsilon_h$, which would account for large negative income shocks, e.g., job loss as documented in Knesl (2018), would increase the magnitude of this risk premium.
The value of firms in the capital-based sector $s = 2$ is defined equivalently as:

$$V^k_{f,s,1} = D^k_{f,s,1} + \mathbb{E}\left[\Lambda_h D^k_{f,s,2}\right]. \quad (20)$$

The expectation operator in the valuation equations 19 and 20 is defined from household $h'$s perspective over both aggregate and idiosyncratic states. The realization of all states and the corresponding probabilities are depicted in figure 1. The stochastic discount factor $\Lambda_h$ takes a different value in each possible realization including the realization of idiosyncratic labor productivity risk $\tilde{\epsilon}_h$. Hence the households’ idiosyncratic risk affects the valuation of assets. The idiosyncratic risk is relevant only when $A^{High}$ is realized. The importance of the idiosyncratic risk is then given by the percentage of firms that automate $\delta^*$. Hence the idiosyncratic risk is state dependent as in Constantinides and Ghosh (2017).

![Figure 1. Households’ Possible States.](https://ssrn.com/abstract=3293405)
D. Equilibria

The equilibrium is defined by the solution of the households’ optimization problem [16] and [13] and market clearing conditions on all markets. The market clearing conditions for product markets at the level of firms and sectors as well as for capital and labor markets are stated in appendix [A].

In the second period, $t = 2$, there is a further condition for a Nash-type equilibrium for the equilibrium percentage $\delta^*$ of firms that automate within sector $s = 1$. Each firm must prefer its choice of the production type given the choices of the remaining firms in the sector. There is a unique equilibrium of one of the following three types.

**Equilibrium 1.** None of the firms in the sector prefers capital-based production, $\delta^* = 0$. The sector remains homogeneous with labor-based firms only. In this equilibrium, inequality [21a] holds. The left-hand side shows the payoff when the firm switches to capital-based production. This payoff consists of dividends and an automation cost. The right-hand side is the dividend of a firm that keeps labor-based production. If the price of capital is high enough, no firm will have an incentive to automate as it leads to lower sales and requires automation cost $\kappa$.

\[
\begin{align*}
\text{a. } & \frac{1}{\nu} P^k_{f,1,2} \left( \frac{P^k_{f,1,2}}{P^l_{1,2} (\delta^*)} \right) - \nu Y_{1,2} (\delta^*) - \kappa \leq \frac{1}{\nu} P^l_{f,1,2} \left( \frac{P^l_{f,1,2}}{P^l_{1,2} (\delta^*)} \right) - \nu Y_{1,2} (\delta^*), \quad \delta^* = 0 \\
\text{b. } & \frac{1}{\nu} P^k_{f,1,2} \left( \frac{P^k_{f,1,2}}{P^l_{1,2} (\delta^*)} \right) - \nu Y_{1,2} (\delta^*) - \kappa = \frac{1}{\nu} P^l_{f,1,2} \left( \frac{P^l_{f,1,2}}{P^l_{1,2} (\delta^*)} \right) - \nu Y_{1,2} (\delta^*), \quad 0 < \delta^* < 1 \\
\text{c. } & \frac{1}{\nu} P^k_{f,1,2} \left( \frac{P^k_{f,1,2}}{P^l_{1,2} (\delta^*)} \right) - \nu Y_{1,2} (\delta^*) - \kappa \geq \frac{1}{\nu} P^l_{f,1,2} \left( \frac{P^l_{f,1,2}}{P^l_{1,2} (\delta^*)} \right) - \nu Y_{1,2} (\delta^*), \quad \delta^* = 1, \\
\text{d. } & P^l_{1,2} (\delta^*) = \left( P^k_{f,1,2} \frac{1-\nu}{\nu} \delta^* N + P^l_{f,1,2} \frac{1-\nu}{\nu} (1 - \delta^*) N \right)^{\frac{1}{1-\nu}} \\
\text{e. } & Y_{1,2} (\delta^*) = \left( Y^k_{f,1,2} \frac{\nu - 1}{\nu} \delta^* N + Y^l_{f,1,2} \frac{\nu - 1}{\nu} (1 - \delta^*) N \right)^{\frac{\nu}{\nu - 1}}
\end{align*}
\]

This equilibrium is shown in the first column (no shock) in figure [2]. Panel A shows the market-clearing prices of goods produced by each type of firm, labor-based and automated, as a function of the percentage of firms that automate $\delta$. The blue line depicts the prices of goods produced by labor-based firms and the red line depicts the equivalent function for automated firms. I select the model parameters so that the lines intersect at $\delta = 0$ if the technology $A_2$ remains constant at $A_{low}$. The prices of goods of automated firms are predominantly increasing in $\delta$. The increase reflects the decreasing returns to scale of the capital installation function [4].

\[\text{[Place Figure 2 about here]}\]
Panel B shows the corresponding demands for the goods of each firm type as functions of $\delta$. The demand for goods of labor-based firms is above the demand for goods of automated firms for $\delta > 0$ as the prices of labor-based firms’ goods are lower in this region. This follows from the demand functions in equations $\ref{eq:10}$ and $\ref{eq:11}$.

Panel C shows the dividends of each type of firm as functions of $\delta$. The dividends of labor-based firms are above the dividends before automation cost of automated firms for $\delta > 0$. This follows from the price elasticity of the demand functions for firm-specific goods $\nu > 1$. The dividends of automated firms are even smaller when the automation cost $\kappa$ is taken into account. Hence the equilibrium percentage of automated firms in sector $s = 1$ is $\delta^* = 0$.

**Equilibrium 2.** A percentage $0 < \delta^* < 1$ of firms in the sector automates and pays automation cost. This equilibrium can be thought of as a mixed-strategy equilibrium where firms choose an optimal probability $\delta^*$ to automate and probability $1 - \delta^*$ to keep the labor-based production. The equilibrium is defined by the equality $\ref{eq:21}$ b. The left-hand side shows the payoff of a firm that automates. The right-hand side is the dividend of a firm that keeps labor-based production. Abstracting from the effects at the sector level, the equality holds when the gain from higher sales due to lower goods prices $\left(\frac{P_{k1,2}^{\delta^*}}{P_{1,2}(\delta^*)}\right)^{\nu}$ exactly counterweights the automation cost $\kappa$. Firms that adopt capital-based production extract higher rents at the cost of firms that keep labor-based production.

The middle column of figure $\ref{fig:2}$ shows this type of equilibria. I assume an incremental improvement in the technology level $A^{High}$. In panel A, the prices of goods of automated firms shift downward and intersect the price function of the labor-based firms. Panel B shows that the changes in prices lead to a higher demand for goods of automated firms relative to labor-based firms if the percentage of automated firms is low enough. Panel C shows the equilibrium percentage of firms $\delta^*$ in sector $s = 1$ that optimally automate production. In the region $\delta < \delta^*$, labor-based firms have an incentive to automate as they will benefit from higher demand. In the region $\delta^* < \delta < \hat{\delta}$, firms do not want to automate as the slightly higher demand for their products does not compensate the automation cost $\kappa$. In the region $\hat{\delta} < \delta$, the demand for goods of automated firms is already below the demand for goods of labor-based firms. Firms are indifferent between keeping the labor-based production and automation only at $\delta^*$.

**Equilibrium 3.** All firms in the sector automate, $\delta^* = 1$. The sector is homogeneous with capital-based firms only, and inequality $\ref{eq:21}$ c holds. This equilibrium arises when the price of capital $P_{1,2}^I$ is low enough. In this case, a firm will experience dramatically lower sales when it keeps the labor-based production given all other firms have automated. Hence all firms optimally adopt the capital-based production despite the automation cost to avoid more severe punishment through lower sales. Abstracting from the effects at the industry level, all firms keep the same rent but pay the automation cost $\kappa$.

This equilibrium is shown in the right-hand side column in figure $\ref{fig:2}$. I assume a large increase in the technology level $A^{High}$. In this case, the prices of goods of automated firms are always below the prices of labor-based firms. This is reflected in the demand function of the automated
firms that is always above the demand function of the labor-based firms. If the improvement in the technology level $A_2$ is large enough, the net dividend of automated firms will be above the dividend of labor-based firms regardless of the percentage of automated firms in the sector. The equilibrium percentage of automated firms is $\delta^* = 1$. Even in this case, the net dividend can be below the original level. All firms in the sector optimally decide to automate even if automation leads to a lower net dividend. Firms which had stuck with the labor-based production would have experienced much lower revenues that is more penalizing than the automation cost $\kappa$. This situation highlights that adopting a relatively cheaper production technology can become a pure necessity to stay competitive and the automation benefits are passed to the final consumers in the form of lower product prices.

Panel A in figure 3 presents the relationship between the magnitude of the technology shock $A^{High}$, conditional on the occurrence of this state, and the equilibrium percentage of automated firms $\delta^*$. This relationship is strictly positive. A higher level of technology $A^{High}$ decreases the prices of capital investment $P_{1,2}$ and makes capital-based production more favorable despite a higher amount of invested capital $I_{1,2}$. I select the model parameters such that the first type of equilibria, $\delta^* = 0$, exists when $A_2 = A^{Low} <= 0.89$. The second type of equilibria, $0 < \delta^* < 1$, emerges when $A_2 = A^{High}$ and $0.89 < A^{High} < 1.05$. The third type of equilibria, $\delta^* = 1$, establishes if the technological change is large enough, $A_2 = A^{High} >= 1.05$.

**E. Implications for Firms Risk Exposure and the Dynamics of Stock Returns**

In this section, I show that a positive technology shock that facilitates automation can lead to an adverse outcome for firms in a sector that is undergoing at least partial automation. The adverse effect of such a shock is equally present among all firms within the sector regardless of whether the particular firm automates or not.

Panel B of figure 3 shows the equilibrium dividends of firms in sector $s = 1$ as a function of the magnitude of the technology shock $A^{High}$, conditional on the realization of this state. In equilibrium, the dividends are identical for all firms in the sector regardless of whether the particular firm automates or not. An increase in the technology shock leads to a lower dividend of every firm in this sector. This relationship is weak for low levels of $A^{High}$ but becomes stronger for higher values of technology improvements. This reflects the convex relationship between the equilibrium percentage of automated firms $\delta^*$ and $A^{High}$ shown in panel A.

A larger technology shock leads to a higher percentage of firms that automate $\delta^*$ and charge lower product prices. This decreases the price of the sector-aggregate good $P_{1,2} (\delta^*)$ as shown in formula 21.d. Since firm’s relative revenues depend on the price of its good relative to the sector-aggregate good $\left( \frac{P_{1,2}}{P_{1,2} (\delta^*)} \right)^{-\nu}$ with $\nu > 1$, it becomes more prohibitive to keep the labor-based production that produces goods at higher relative prices. At the same time, the rents of automated firms decrease as the prices of their goods and the price of the sector-aggregate good come closer.

---

15I plot the firms’ dividends as a function of the equilibrium percentage of automated firms $\delta^*$ in online appendix figure IA. This relationship becomes generally linear.
to each other. Automation becomes a costly necessity to stay competitive.\footnote{This statement abstracts from inter-sectoral demand shifts. The inter-sectoral demand shifts are considerably smaller as the sector-level goods are weaker substitutes.}

[Place Figure 3 about here]

Panel C shows the effect of technology shocks on dividends of firms in sector $s = 2$. This relationship is strictly positive. Since this sector already consists of firms with capital-based production, the firms are not exposed to strategic considerations of costly adoption of technology that would decrease their dividends. Hence firms in sector $s = 2$ benefit directly from lower prices of capital investment $P_{2,2}^I$ brought by a higher level of technology.

In this model, the effect of a technology shock on dividends translates directly to firms’ risk exposure to the shock. I plot the risk exposure of firms in each sector as functions of $A^{High}$ in panel A of figure 4. Firms in sector $s = 1$ have negative exposure to technology shocks. The magnitude of the exposure is low for low values of $A^{High}$ but increases dramatically. Hence a technology shock decreases the firm value of firms in this sector. These firms experience negative return on the impact of technology shock. Firms in sector $s = 2$, which consists entirely of capital-based firms, have positive exposure and experience positive stock return upon the occurrence of technology shock. Differences in stock returns between firms in these two sectors can then be informative about technology shocks embodied in capital. This outcome holds also if the model includes an additional factor neutral productivity shock as such shock would have exactly the same effect in each sector.

[Place Figure 4 about here]

The results in this section show that firms partly compete away potential rents from technological progress, and thus the benefits of technology shocks are captured primarily by final consumers. Competition among firms forces them to undergo costly automation process although its benefits are passed through to the consumers. Firms with labor that can be automated by capital then exhibit negative risk exposure to technological progress that facilitates such automation.

F. Implications for Stock Return Premium

In this section, I show that the differences in firms’ exposure to technology shocks are associated with differences in expected stock returns as the risk of technology shocks is priced by the households.

First, I emphasize that the model is able to generate both negative and positive premium for the risk of technology shock that facilitates automation. The sign of the premium is determined by the dispersion of the idiosyncratic labor productivity shock $\epsilon$, which households face upon the occurrence of the technology shock and the associated possible job movement. Figure 5 shows the relationship between the dispersion of the idiosyncratic labor productivity $\epsilon$ and the risk premium.
of an asset $E[R^t] - R_f$ that has $\beta = 1$ exposure to the technology shock $A_2$. Households require a positive premium for this asset if the idiosyncratic labor productivity risk $\epsilon$ is low. In this case, the higher average labor productivity of spouses working in the capital production due to $A^{High}$ dominates the idiosyncratic labor productivity risk. As $\epsilon$ increases, the idiosyncratic labor productivity risk dominates and the return premium becomes negative. In this case, households dislike the occurrence of technology shock as they may experience a severe decrease in their labor income. The same asset becomes valuable as it outperforms upon the occurrence of the technology shock.

[Place Figure 5 about here]

For the following analysis, I assume the case of negative premium. This assumption aligns with empirical evidence from the U.S. stock market over the last four decades, which I provide in later sections. The relativity of the return premium described in figure 5, however, highlights that the implications of technology shock for expected stock return depend on the particular economic environment, in this case the households’ ability to stay productive in new occupations. Hence, evidence from other countries can be particularly valuable.

Panel B in figure 4 shows the expected stock returns of firms in each sector as functions of the magnitude of the technology improvement $A^{High}$. Firms in sector $s = 1$ earn higher expected return than firms in sector $s = 2$. This follows directly from the firms’ exposure and the assumption of negative risk premium. Firms in sector $s = 1$ have a negative exposure (see panel A) to a negatively priced risk which results in high expected returns. The positive exposure of firms in sector $s = 2$ to the same risk leads to lower expected returns.

The difference in the expected returns between firms in sector $s = 1$ and $s = 2$ increases with the magnitude of $A^{High}$ as shown in panel C. This follows from the changes in the exposure of firms in sector $s = 1$ as shown in panel A and from the increase in the premium. The exposure of firms in sector $s = 1$ becomes more negative as $A^{High}$ increases, while the exposure of firms in sector $s = 2$ remains almost constant. The magnitude of the premium also increases. Higher $A^{High}$ increases the equilibrium number of automating firms and thereby the likelihood of displacement for households. The increasing differences in the exposure of firms in each sector together with the increasing magnitude of the premium lead to similarly increasing differences in expected return.

II. Data

A. Measuring Firms’ Share of Displaceable Labor, The Automation Potential

The main input in my analysis is a measure of firms’ share of displaceable labor, the Automation Potential (AP). I use the occupational characteristics from the O*Net database, the composition of labor force from Occupational Employment Statistics (OES) and the relative importance of labor and capital to calculate the AP measure at the firm level. The AP measures the relative importance of labor that can be easily replaced by capital.
I measure firm $j$’s AP at time $t$ as:

$$AP_{j,t} = \ln \left( \frac{L_{j,t}^{\text{routine}}}{K_{j,t}} \right)$$  \hspace{1cm} (22)

The numerator of the AP formula, $L_{j,t}^{\text{routine}}$ measures the number of employees in routine intensive occupations, i.e., labor that can potentially be substituted by capital. The number of firm’s employees is available for each firm and the occupational composition is imposed to individual firms from a detailed industry level from the OES. To assess the relative importance of routine labor in the production process, I divide this labor by firm’s capital. Firms with a high AP measure correspond to firms in sector $s = 1$ in the theoretical model. These firms have large potential to displace labor by capital. Firms with a low AP measure correspond to firms in sector $s = 2$. These firms either have a lot of capital and/or their labor is non routine and complements capital. I carefully examine a range of alternative specifications of the AP formula and discuss them in detail below. I describe further details of the construction of the AP measure in appendix C.

I measure the potential of replacing human workers by capital in each occupation by the Routine Task Intensity measure (RTI). This measure was originally developed by Autor and Dorn (2013) and measures the importance of routine, abstract and manual tasks in each occupation. High RTI scores indicate high importance of routine tasks in a given occupation. Routine tasks are defined as tasks that can be accomplished by following a precise set of rules and potentially be executed by machines programmed to follow this set of rules. Low RTI scores indicate low importance of routine tasks and high importance of abstract and manual tasks, which cannot easily be performed by machines.

The original measure was calculated for 330 occupations based on data from the Dictionary of Occupational Titles (DOT) 1977. I develop a new and more detailed version of the RTI measure based on occupational characteristics from the majority of the O*NET database releases. I describe the structure and the data collection procedure of the O*NET database in appendix B. This approach significantly improves the RTI measure in several dimensions. First, I use multiple releases of the O*NET database, which allows the new RTI measure to capture the changes in the occupational characteristics within occupations over time. Technological progress and automation are likely to change the nature of some occupations over time. Autor et al. (2003) show that occupations that increased the use of computers significantly reduced the input of routine tasks and became more nonroutine. This evidence stresses the importance to account for changes in

\[\text{17}\] The term production process is used broadly in this context. It refers not only to physical production but also to all operations of a given firm including firms in service sectors that do not necessarily produce physical products.

\[\text{18}\] Autor et al. (2003) developed the original underlying data for the RTI measure and define the routine tasks as follows: ‘In our usage, a task is “routine” if it can be accomplished by machines following explicit programmed rules. Many manual tasks that workers used to perform, such as monitoring the temperature of a steel finishing line or moving a windshield into place on an assembly line, fit this description. Because these tasks require methodical repetition of an unwavering procedure, they can be exhaustively specified with programmed instructions and performed by machines.’

\[\text{19}\] I find supportive evidence for changes in the RTI measure within occupations in online appendix figure A.3.
occupational characteristics over time. Second, I calculate the RTI measure for a larger number and more detailed occupations. Depending on the release of the O*NET database, I calculate the RTI measure for 654-731 occupations.\footnote{I report the exact number of occupations in each O*NET release for which I calculate the RTI measure in table IA.2.} Third, I use a larger set of underlying occupational characteristics (30 instead of 5) to measure the importance of routine, abstract and manual task inputs. The wide range of the characteristics provides a robust measurement of the importance of each type of tasks. It allows for changes in task inputs within occupations to be easily detected over time as some occupations may change only one characteristic while keeping others constant. This approach also addresses a possible bias in selecting suitable characteristics to measure the importance of tasks inputs.\footnote{Acemoglu and Autor (2011) also construct RTI measure based on the O*NET database version 14.0. The approach and the selection of the underlying descriptors is similar and my RTI measure strongly correlates with the RTI measure in this paper. The main distinction is that I utilize the updates of the O*NET database as well as the original data from the Dictionary of Occupational Titles included in the first releases of the O*NET database. This allows me to account for the changes within occupations over time and avoid carrying over possible measurement errors to other years.}

To calculate the RTI measure, I select 30 occupational descriptors and group them into descriptors measuring abstract, routine and manual tasks. I report the full list of the descriptors including the corresponding scales of measurement in online appendix table IA.3. I calculate the routine, abstract and manual task inputs for each occupation by averaging the scores of the corresponding descriptors as follows

$$T_{occ,t}^j = \frac{1}{N_j} \sum_{i \in N_j} \text{Descriptor}_{occ,t,i}$$

$$j \in \{\text{Routine, Manual, Abstract}\}, \quad (23)$$

where $T_{occ,t}^j$ is the input of task $j$ in occupation $occ$ at time $t$ and $N_j$ is the set of descriptors for $j$'s task input. Using the task inputs, I calculate the RTI for each occupation as

$$RTI_{occ,t} = \ln(T_{occ,t}^R) - \ln(T_{occ,t}^M) - \ln(T_{occ,t}^A)$$

(24)

Occupations with a high RTI score predominantly consist of routine tasks and hence have high potential to be automated by machines. Occupations with a low RTI score require strong input of abstract or manual tasks, such as critical thinking, active learning, negotiation or operating vehicles and hence cannot easily be automated. I report the summary statistics of the RTI scores and the underlying task inputs at the level of occupations in online appendix table IA.4. To provide examples of the most routine and non-routine occupations, I list representative routine and non-routine occupations in online appendix table IA.5. These occupations are selected to represent the typical occupations with low and high RTI scores.\footnote{Since the RTI score changes for each occupation over time, I select representative routine and non-routine occupations with high and low RTI score, respectively, in multiple years. Full lists and detailed descriptions of the most routine and nonroutine occupations in individual releases of the O*NET database are omitted from online appendix due to the large size of these tables and are available upon request.} It is important to note that the routine task
intensity is not the same dimension as labor skill dimension. Routine occupations are generally concentrated in the middle skill-level occupations with average labor income (see e.g. Autor and Dorn (2013)). I provide empirical evidence supporting the robustness and validity, and discuss potential shortcomings of the new RTI measure in appendix C.

The AP measure can vary between industries, as well as across firms within the same industry. The majority of the variation, however, is at the between-industry level. Table I reports the summary statistics and variance decomposition of the AP measure into within- and between-industry variation. Panel A shows that there is a considerable variation in the share of displaceable labor measured by the AP measure at the firm level across firms in all industries and the results in panel B show that similar variation is present also when firm level observations are aggregated at the industry level, i.e. variation between industries. Panel C then shows formally that the majority of the variation in the AP measure is due to between-industry variation, as it accounts for about 70% of the total variance. This result indicates that the automation potential measured by the ratio of routine labor to capital is a predominantly industry-specific characteristic. I list the industries with the lowest and highest automation potential, as defined by the AP measure in online appendix table IA.7.

The dominance of the between-industry variation in the AP measure supports the modeling focus in my theoretical model where firms have ex ante same production function within the industry but differ strongly from firms in other industry. I show later in the paper that this between-industry variation in the AP measure is also the primary source of the co-movement between stock returns of firms sorted by the AP measure and technology shocks embodied in capital goods. Despite the dominance of the between-industry variation, within-industry variation can play an important role as well. Zhang (2018) analyzes the within-industry variation of displaceable labor share with respect to firm’s real hedging options.

I next establish the relationship between the AP measure and two other potential measures. First, I use the total number of all employees instead of the total capital in the denominator of the AP measure, i.e. \( \text{Routine intensity}_{j,t} = \ln \left( \frac{L_{\text{routine}}}{L_{\text{total}}} \right) \). Second, I use the number of all employees instead of employees in routine occupations in the numerator. This measure is in essence a firm’s labor intensity, i.e. \( \text{Labor intensity} = \ln \left( \frac{L_{\text{total}}}{K_{j,t}} \right) \). These two measures are positively correlated with each other. Online appendix figure IA.2 shows that the correlation is strong except for the 1990s when the sample was inflated by a large number of new dot-com firms that lacked typical production facilities. The strong relationship between these two measures has re-established again since 2005. Due to this strong relationship, both measures sort firms and industries cross-sectionally in a very comparable way in most of the years examined.

Another interesting fact shown in Abis (2017) is the ongoing pervasion of computing technology and algorithmic trading relative to discretionary human-based trading in fund management industry, which generally includes high-income workers.
I also examine the importance of different types of capital in the denominator of the AP measure. Specifically, I use only equipment or equipment and intellectual products and property instead of a firm’s total capital to address a potential concern that the total capital in some industries is dominated by structures. I also account for the changes in the composition of equipment over time on the basis of the real stock of 64 different types of equipment. This addresses the potential concern that some industries significantly increased the real stock of equipment, such as ICT equipment, whose real prices decreased over time and hence an increase in the real stock would not be reflected in firm’s total nominal capital reported in Compustat. None of these variations are essential for the subsequent analysis. The results in the following sections are robust to the use of these alternative AP measures.

B. Financial Data

I focus on common stocks of firms listed on NYSE, NASDAQ, and AMEX from 1970 to 2015 and use monthly data from the Center for Research in Security Prices (CRSP). To calculate the AP measure, I require the firms to have underlying data for the number of employees and total net capital in the Standard and Poor’s Compustat database. I exclude financials SIC 6000-6799, utilities SIC 4900-4999, and public sector companies SIC $\geq 9000$. Hou, Xue, and Zhang (2017) find that a large number of previously documented cross-sectional return anomalies are strongly driven by micro-cap stocks and these anomalies are hardly replicable when the sample excludes micro-cap stocks. To address this concern, I exclude small and illiquid stocks as well as stocks with short history from my sample. I describe the applied filters in detail in appendix D. None of these filters are essential for the documented results. The final sample contains a total of 8,150 unique firms. I also redo my analysis on the basis of S&P 500 stocks and find quantitatively and qualitatively very similar results. The results based on the constituents of S&P 500 are presented in online appendix.

C. Measuring Technology Shocks Embodied in Capital

I measure the technology shocks embodied in capital by the changes in quality adjusted relative prices of investment goods. The formal theoretical validity of this measure has been derived in previous literature, e.g., Greenwood et al. (1997); Cummins and Violante (2002); Hornstein and Krusell (1996) (see appendix E for a parsimonious theoretical foundation based on these papers). This measure has been used in a number of previous studies, e.g., Greenwood et al. (1997), Greenwood et al. (2000), and Fisher (2006). The intuition behind the theoretical foundation of this measure is that investment-specific technology shocks allow for production of new capital goods, such as machines, software or equipment, at lower cost or with higher quality. Hence the changes in the quality adjusted prices of capital goods relative to aggregate prices are informative about the technological progress. As in previous literature, I construct the measure of technology shocks embodied in capital (I-shock measure) by subtracting the log changes in the quality-adjusted prices.

\[ \text{I-shock measure} = \log(\frac{\text{Quality adjusted capital goods}}{\text{Aggregate prices}}) \]

I use the BEA classification for the different types of equipment. I account for the differences in capital composition at the level of BEA code industries.
of capital goods from the log changes in the aggregate price level. An increase in the I-shock measure indicates a positive technology shock and is associated with higher quality and/or lower prices of capital goods.\footnote{I also extract the innovations in the I-shock measure $\epsilon^t_I$ from $Ishock_t = \alpha + \rho \times Ishock_{t-1} + \epsilon^t_I$. The results based on the innovations $\epsilon^t_I$ are practically same to those based on the I-shock measure itself.}

The underlying price indexes are from the U.S. Bureau of Economic Analysis (BEA). I measure the aggregate price level by the price index of the personal consumption expenditures for nondurable goods. The quality-adjusted prices of capital goods are based on the price index for private fixed investment in nonresidential equipment. This price index is a combination of price indexes of 25 different types of equipment. I use annual frequency for both time-series and calculate the I-shock measure from 1970 to 2015.

Since the I-shock measure is based on quality adjusted prices of capital goods, it is important to account for the changes in quality of goods in the underlying price indexes. The increase in the horsepower of cars and increases in the processing power and memory of computers over recent decades are prominent examples of large quality changes of goods. Ideally, quality-adjusted price indexes take the changes of quality into account and express the price per efficiency unit. Several earlier papers, e.g. Griliches (1961); Gordon (1990), point out the lack of an appropriate quality adjustment of the NIPA price indexes of equipment. The BEA has addressed the problem of quality adjustment over the last three decades and developed price indexes that account for quality changes using various techniques such as hedonic regressions. The price indexes of fast improving types of equipment such as computers and peripherals have used hedonic-based quality adjustments since the 1980s. I further account for possible quality changes by using the quality adjustment from Cummins and Violante (2002). This adjustment accounts for the measured quality difference in the underlying components of the price index of capital goods from Gordon (1990) until 1983 and extrapolates the adjustment to recent years.

Consistent with previous literature, e.g. Fisher (2006), I document a positive mean of the I-shock measure, indicating a secular trend of decreasing prices and increasing quality of capital goods. I provide a full set of summary statistics of the I-shock measure in online appendix table IA.10. The I-shock measure correlates strongly with the TFP shock of industries producing the capital goods. The correlation with TFP shock of industries producing consumption goods is practically zero. This result is in line with the theoretical foundation of this measure. The correlation with the aggregate TFP shock is negligible. This reflects the fact that industries producing capital goods comprise a relatively small part of the U.S. economy. The I-shock measure has a positive correlation with the GDP growth. This is consistent with previous papers showing that prices of capital goods are an important driver of economic growth, Fisher (2006); Greenwood et al. (2000).

The dashed blue line in figure 6 plots the normalized time-series of the I-shock measure from 1970 to 2015. I normalize the I-shock measure to mean zero and standard deviation of one to facilitate

\footnote{Wasshausen, Moulton, et al. (2006) provide a brief overview of the use of hedonic methods by the BEA to measure real GDP; Fox and McCully (2016) provide detailed information about the price indexes for all types of equipment and discusses the quality adjustments employed by BEA.}
comparison with other time-series later in the paper. Since the original I-shock measure has a
significantly positive mean of 4.0, a zero value of the normalized measure still indicates a positive
technological progress. The most prominent and pervasive technology shock during this period
was from 1997 to 2001. During these years, the normalized I-shock measure recorded a cumulative
increase of 5.71 standard deviations. This increase was driven mainly by a large drop in the quality-
adjusted prices of information processing equipment. The prices of this equipment decreased by 40
percent, while the prices of consumption goods measured by personal expenditures for nondurables
increased by 8 percent. Since information processing equipment accounted for about one third of
total private investment, the aggregate price index of capital goods decreased by ca 15 percent. The
massive drop in the prices of information processing equipment can be tracked back to a significant
productivity growth (TFP shock) in a single manufacturing industry. The electronic computer
manufacturing industry (NAICS code 334111) recorded an increase in productivity of 216 percent.
This was accompanied with a decrease in the industry’s shipment prices by ca 80 percent and an
increase in its shipments by ca 380 percent. The remaining manufacturing industries, including
consumption goods producers, experienced only moderate productivity growth of 5.33 percent.

I link all other major shocks in the I-shock measure to a differential productivity growth of
a small number of capital-goods producing industries in online appendix table A.11. Positive
technology shocks mark always relatively higher productivity growth of a small number capital
goods producing industries and are accompanied by relatively lower prices and higher quantity of
shipments from these industries. This evidence provides validity to the theoretical foundation of
the I-shock measure as an appropriate measure of technology shocks embodied in capital goods.
Two periods marked by the I-shock measure as important technology shocks have been studied in
a number of previous papers. For example, Pastor and Veronesi (2009) explain the stock market
bubble-like pattern in the late 1990s and its burst afterwards by a substantial adoption of IT
technology starting in the late 1990s. Hobijn and Jovanovic (2001) argue that arrival of important
technological innovations, e.g., microprocessor, in the early 1970s led to subsequent decrease in the
aggregate stock market. Similarly, Greenwood and Yorukoglu (1997) argue that a large technology
shock embodied in capital goods during the early 1970s is at the origin of a range of subsequent
economic phenomena including income inequality.

D. I-shock as an Income State Variable

I show in a companion paper Knesl (2018) that technology shocks embodied in capital, measured
by the changes in relative prices of capital goods, are an important source of job-displacement and
labor-income risk. Lower prices and higher quality of capital goods allow substituting capital for
labor in occupations that have the potential to be automated. Hence, technology shocks embodied
in capital are an important state variable indicating the risk in labor income of households. This

27 The solid red line is a factor mimicking portfolio that is described in sections II
28 The calculations are based on the data from the NBER-CES Manufacturing Industries database Bartlesman and
result is consistent with other papers investigating the impact of innovation and technological progress on labor income, e.g., Kogan et al. (2017). I provide a concise illustration of this result below. I refer the reader to the papers mentioned above for detailed results.

Panel A of table II reports the results of regressing contemporaneous and future log growth in personal income per capita and cross-sectional average of income growth on the I-shock measure and the aggregate productivity shock (TFP). Specifically, I estimate the regression of this form

\[
\frac{1}{K+1} \sum_{k=0}^{K} y_{t+k} - y_{t+k-1} = \alpha + \gamma_{Ishock} \times Ishock_t + \gamma_{TFP} \times TFP_t + \epsilon_{t+k};
\]

where \( y_{t+k} - y_{t+k-1} \) is the log growth rate in average income per capita from the U.S. Bureau of Economic Analysis or cross-sectional average of personal income growth from Guvenen, Ozkan, and Song (2014). \( Ishock_t \) is the I-shock measure representing the change from \( t-1 \) to \( t \). The \( TFP_t \) is the change in the aggregate productivity over the same time period. I estimate the regression at annual frequency for time horizons \( K = 0, 1, \) and \( 2 \). The results are robust to controlling for lagged dependent variable and alternative specifications. The first three columns of panel A show that a positive technology shock embodied in capital (I-shock) is associated with a slightly lower growth in average income per capita, an effect that becomes significant at the horizon of two years. The next three columns provide a similar results for the average of cross-sectional personal income growth for data from Guvenen et al. (2014).

Although the results in panel A suggest a somewhat adverse of effect of technology shocks on income growth, looking only at the aggregate or average income growth can hide potentially important effect of technology shocks on individual personal income growth. To examine the effect of the I-shock on higher moments of cross-sectional distribution of individual income, I estimate the regression equation 25 with changes in the standard deviation and skewness of the cross-sectional distribution of individual income growth as the dependent variable using the data from Guvenen et al. (2014). Panel B of table II presents the estimates. The first three columns show that the standard deviation increases only slightly following a positive I-shock. The last three columns show that a decrease in prices of capital goods, a positive technology shock, has the most negative effect on the skewness of individual income growth. A positive technology shock embodied in capital significantly increases the left skewness of the income growth distribution. Individuals are more likely to experience large drops in personal income in years following a positive I-shock.

This result is in line with Knesl (2018) in showing that a positive I-shock increases the probability of losing job. Large negative idiosyncratic shocks to income growth such as job loss are

\[^{29}\text{I use nominal personal income to avoid a potential mechanical effect of deflating as the I-shock measure contains changes in prices of consumption goods in its numerator. The estimation results based on nominal personal income represent lower bound.}\]

\[^{30}\text{Estimating the regression equation 25 with levels of the central moments as dependent variables provides similar results. The results are similar when I control for lagged dependent variable.}\]
then pronounced in higher moments of income growth distribution as shown above. This supports the assumption of the state-dependent idiosyncratic labor productivity risk in the theoretical model presented earlier. Higher moments of the cross-sectional distribution of individual income growth play a central role in pricing assets in incomplete markets when agents face uninsurable income risk. In the seminal work, Constantinides and Duffie (1996) derive a theoretical model of incomplete markets with heterogeneous agents and uninsurable idiosyncratic income risk where the second moment of the cross-sectional distribution of individual labor income enters the stochastic discount factor. Constantinides and Ghosh (2017) show that the third central moment of individual income growth drives asset prices and risk-free rate. Schmidt (2016) provides evidence that the idiosyncratic tail risk of income growth is state-dependent and predicts stock returns, and further shows that a model with state-dependent, time-varying idiosyncratic disaster risk and incomplete markets matches key asset pricing moments.

III. Technology Shocks and Displaceable Labor

A. Co-movement

I sort stocks into five portfolios based on their share of displaceable labor (AP) to examine the time-series and cross-sectional properties of stock returns associated with firms’ automation potential. I report the summary statistics of firm characteristics in each portfolio in online appendix table IA.14. The first portfolio consists of stocks with the highest AP. These firms also have high average labor intensity and a high percentage of employees in routine occupations. The average AP measure then decreases from -2.9 in the first portfolio to -5.9 in the fifth portfolio. The portfolios are rebalanced annually at the end of June and portfolio returns are value-weighted unless stated otherwise.

![Place Figure 6 about here]

Figure 6 plots the I-shock measure and the annual stock return difference between firms with low and high displaceable labor share, i.e. long-short portfolio with a long position in the bottom quintile of firms ranked by the AP measure and a short-position in the top quintile, the KML portfolio. These two time-series co-move very strongly and overlap in all spikes. The correlation coefficient is 0.60. This strong co-movement is a robust feature of the data and it is present across various samples of firms. It holds when I exclude firms producing capital goods from the sample and it is present independently among both, manufacturing and non-manufacturing firms. The co-movement is also not driven by firms’ operating leverage or size (see figure IA.4 and table IA.21 in the online appendix for the long-short portfolio consisting of firms in these samples as well as portfolios controlling for operating leverage and size). This result indicates a strong connection

---

31 The theoretical model in Constantinides and Ghosh (2017) assumes that households’ consumption equals households labor plus dividend income, where the labor income is subject to uninsurable idiosyncratic shock. The model is estimated using individual consumption data from the Consumer Expenditure Survey.
between a macroeconomic variable measuring changes in quality-adjusted capital goods prices and the dynamics of stock returns. The finding supports the prediction of the theoretical model that technology shocks embodied in capital lead to different stock price reactions between firms with low and high share of displaceable labor. The strong co-movement of the KML portfolio and the I-shock measure over the last 45 years shows that the stock return differences between these two types of firms have been informative about capital-embodied technology shocks as implied by the model.

I first examine whether the co-movement of the KML portfolio with the I-shock measure is driven by ranking individual firms relative to industry peers or by ranking whole industries across the economy. Table III reports the correlation coefficients between the I-shock measure and the long-short portfolios based on the within- and between-industry variation in displaceable labor share, AP. The correlation is strong, 0.53-0.59, for long-short portfolios based on ranking whole industries. It is weak for long-short portfolios of firms ranked relative to industry peers. This is in agreement with the dominance of the between-industry variation in the AP measure discussed above (see panel C in table I). Both pieces of evidence underline the role of displaceable labor share as an industry characteristic. This also highlights the different focus of this study from the analysis in Zhang (2018). Ben Zhang focuses solely on the variation of displaceable labor within industries in a framework that abstracts from the role of technology shocks. Instead, my interest centers on the importance of technology shocks embodied in capital for firms with displaceable labor. The importance of these shocks is suggested by the strong co-movement between the I-shock measure and the return differences between firms sorted by the share of displaceable labor at the level of industries, as opposed to within industries.

I next examine how the exposure to technology shocks varies across the five portfolios. Panel A of table IV reports the results from regressing annual portfolio returns on a constant and the I-shock measure. The first portfolio, consisting of stocks with the highest share of displaceable labor, has the strongest and most negative exposure to technology shocks. The estimated coefficients are negative for all five portfolios. They increase monotonically across all portfolios from -3.4 for the first portfolio to -1.0 for the fifth portfolio. The estimated coefficients are economically large and statistically significant for the first four portfolios. This result indicates that the strong co-movement of the KML portfolio with the I-shock measure is generated by stocks with a high share of displaceable labor. These stocks react negatively to technology shocks. The KML portfolio, i.e., Low-High AP, then exhibits positive and significant exposure to technology shocks of 2.3.

Garlappi and Song (2016) use also an alternative macroeconomic low frequency measure of capital-embodied technology shocks, $g_{IMC}$, that is constructed as differences in the log growth rate of aggregate investment and aggregate consumption. I show in the appendix figure IA.5 that the KML portfolio co-moves closely also with this alternative $g_{IMC}$ measure.

I show in the appendix table IA.22 that regressing the portfolios on the alternative $g_{IMC}$ measure of Garlappi and Song (2016) provides similar results. Firms with the highest share of displaceable labor have the most negative exposure to this measure they also generate most of the co-movement of the KML portfolio with the $g_{IMC}$ measure.
Panel B in table IV repeats the analysis controlling for the aggregate market return. The first portfolio has still the strongest and most negative exposure to technology shocks. The pattern of the estimated coefficients remains monotonic across the portfolios. A notable difference is that all coefficients of the I-shock measure are shifted up so that the fifth portfolio has a positive and significant exposure. The coefficients of the I-shock measure across the first three portfolios remain negative and statistically and economically significant. The KML portfolio has a positive and significant exposure to technology shocks of same magnitude, 2.4. The major part of this exposure, 1.6, comes again from the short position in the first portfolio consisting of firms with high share of displaceable labor.

Regressions in panel C control additionally for the size (SMB) and value (HML) factors as defined by Fama and French (1993). The results are very similar. The estimated coefficients of the I-shock measure increase monotonically across the portfolios from -1.4 for the first portfolio to 0.56 for the fifth portfolio. These results show that standard factors cannot explain the differential exposure to technology shocks across portfolios containing firms with low and high displaceable labor share. I show in online appendix table IA.13 that the results are also not driven by the profitability and investment factors of Fama and French (2015), the return difference between capital goods and consumption goods producers (IMC) of Papanikolaou (2011) and aggregate economic growth.34

The findings in this section document that technology shocks embodied in capital have a strong and negative impact on firms with a high share of displaceable labor. These firms are generally labor-intensive with relatively low capital but high use of labor that can be easily automated. Firms with low share of displaceable labor usually have high capital or not easily replaceable labor and weak or slightly positive exposure to technology shocks. The results on firms’ exposure presented in this section support the predictions of the theoretical model. Consistent with the model, the KML portfolio appears as an empirically capable measure of technology shocks embodied in capital.

B. Firms’ Exposure to Technology Shocks

The previous section shows that consistent with the model the stock return differences between firms with low and high share of displaceable labor, the KML portfolio, strongly correlate with the time-series of technology shocks, the I-shock measure. I use the KML portfolio to estimate firms’ exposure to technology shocks directly from the stock returns. Specifically, for each firm I estimate

34It is interesting that although the IMC portfolio does not have a significant coefficient in the regressions of the first four portfolios in the appendix table IA.13, it has a positive and significant coefficient in the regression of the last portfolio, which consists primarily of capital-intensive firms with a low share of displaceable labor. Kogan and Papanikolaou (2013, 2014) study how investment shocks measured by the IMC portfolio affect the efficiency of investment in capital and thereby benefit firms with growth opportunities. Consistent with their theory, Knesl (2017) shows that the effect of the IMC portfolio is concentrated primarily among firms with capital-intensive growth opportunities as opposed to firms with labor-intensive growth opportunities. The evidence that most of the co-movement of the KML portfolio with the I-shock measure comes from labor-intensive firms with a high share of displaceable labor highlights the complementarity between the IMC and KML portfolios.
the exposure to technology shock, $\beta^{KML}_i$, from a rolling regression:

$$r_{i,t} = \alpha_i + \beta^{KML}_i r_{KML,t} + \epsilon_{i,t}, \quad (26)$$

where $r_{i,t}$ denotes firm $i$’s monthly excess return and $r_{KML,t}$ is the monthly return on the KML portfolio. I estimate this regression for every stock in the sample each year at the end of June using monthly returns over the last 60 months. This method allows the $\beta^{KML}_i$ vary over time. The results reported below are robust to including market excess return and the size, and value factors of Fama and French (1993) as control variables in regression equation (26).

As mentioned earlier, technology shocks are a significant source of labor-income and job-displacement risk. The I-shock measure is a state variable indicating the labor-income and job-displacement risk, especially the risk of large adverse idiosyncratic events such as job loss that are pronounced in the higher moments of the income growth distribution. The $\beta^{KML}_i$ measures stock’s exposure to the labor-income risk directly from the covariances of the returns with the state variable. Hence, sorting stocks on the $\beta^{KML}_i$ is conceptually different from sorting stocks on the share of displaceable labor, $A_P$. Although these two variables are related and correlate strongly, $\beta^{KML}_i$ captures directly stock $i$’s co-movement with a state variable that is highly relevant for investors marginal utility. The differences between sorting on characteristics and sorting on covariances has been discussed in number of previous studies, e.g. Daniel and Titman (1997).

I next examine the properties of the portfolios sorted by the $\beta^{KML}_i$. Each year at the end of June, I sort stocks into five portfolios by their $\beta^{KML}_i$ and hold the stocks in a given portfolio from July of year $t$ to June of year $t + 1$. Panel A of table V reports the post-ranking exposure to the I-shock measure across the portfolios. The exposure is estimated from regressing each portfolio’s annual value-weighted return on a constant and the I-shock measure. The first portfolio consisting of stocks with low $\beta^{KML}_i$ has strongly negative and significant exposure to the I-shock measure. The coefficients are then increasing, absolute values are decreasing, across the portfolios almost monotonically. The sole exception is the second portfolio, which has slightly more negative exposure to the I-shock measure than portfolio one. This result shows that $\beta^{KML}_i$ successfully estimates firms’ exposure to the underlying state variable, the I-shock measure. Firms’ exposure to the KML portfolio predicts the exposure to the I-shock measure at horizon of at least one year. Panel B shows additional properties of stocks within each portfolio. The fifth portfolio contains stocks with relatively low share of displaceable labor compared to stocks in portfolio one. This is consistent with low displaceable labor-share firms having weaker exposure to technology shocks.

I require the stock to have at least 30 observations in the last 60 months.

The results are also robust when the KML portfolio is orthogonalized to the factors of Fama and French (1993).

I show the time-series of the contemporaneous correlation between the share of displaceable labor $A_P$ and the $\beta^{KML}_i$ at firm and industry level in appendix figure IA.6.
IV. Exposure to Technology Shocks and Return Premium

In this section, I investigate whether a stock’s expected return is related to the exposure of its returns to technology shocks, $\beta^{KML}$. I estimate the stock return premium using the cross section of stocks. Then I examine the time variation and predictability of the premium. Finally, I show that stocks exposure implies differential employment and investment behavior and financial underperformance consistent with the mechanism in the model.

A. Return Premium

To examine whether differences in stocks’ exposure to technology shocks are associated with differences in their average returns, I sort stocks into five portfolios according to their $\beta^{KML}$ as described in the previous section. For each portfolio, I calculate a time-series of monthly portfolio returns as value-weighted average returns (unless stated otherwise) across all stocks in the portfolio in a given month. The sample period is from 1975 to 2015.\footnote{The first five years 1970-1975 are used to estimate the $\beta^{KML}$ for portfolios formed in June 1975.}

Panel A of table VI reports the average annualized portfolio excess returns. The first portfolio has the highest average excess return, 12.45%. This portfolio consists of stocks with the most negative $\beta^{KML}$. The average excess returns decrease monotonically across the portfolios. The long-short, High-Low $\beta^{KML}$, portfolio earns a negative premium of -6.85% per year. This premium is statistically and economically significant.

The results are very similar for equally-weighted portfolio returns, reported in panel B. The average excess returns decrease monotonically across the portfolios, although the return differences are smaller. This results in a somewhat smaller return premium of the High-Low $\beta^{KML}$ portfolio, -4.29% per year. The return premium is still statistically and economically significant.

I next examine whether the return differences can be explained by different exposures to aggregate market risk. Panel C reports the results of regressing the monthly portfolio returns on a constant and the market excess return. The estimated intercepts, alphas, exhibit similar pattern as average excess returns. The first portfolio has the highest alpha of 2.97% per year. The alphas decrease monotonically across portfolios. The High-Low $\beta^{KML}$ earns a significant and negative alpha of -5.39%. Although the estimated coefficients of the market returns decrease somewhat across the portfolios, the differences in exposure to aggregate market risk cannot explain the differences in average returns.

Panel D reports estimates of regressions that include also the size (SMB) and value (HML) factors of Fama and French (1993) to control for potential exposure to these factors. The estimated
alphas are slightly smaller in their magnitude when compared to panel C, but the overall result is similar. The alphas decrease across the portfolios almost monotonically. The only exception is the second portfolio, whose alpha marginally exceeds the alpha of the first portfolio. The alpha of the High-Low $\beta^{KML}$ portfolio is -3.6% and is significant at the 10% level. Although the coefficients of the SMB factor also decrease across the portfolios, the differences in the exposure to the SMB factor do not explain the return premium. The pattern in the SMB coefficients is consistent with the evidence in table V indicating increasing stock size across the portfolios.

I repeat this analysis for the constituents of the S&P500 index, which are the largest and most liquid stocks in the U.S. stock market. The results are very similar. They indicate a return premium for High-Low $\beta^{KML}$ portfolio between -7.16% and -4.75% (see table IA.15 in the online appendix). Hence, the results do not depend on the presence of small and illiquid stocks.

I next use panel regressions with firms’ annual stock returns to differentiate the return premium for stocks’ exposure to technology shocks, $\beta^{KML}$, from well-known cross-sectional return predictors. Specifically, I run panel regressions at the firm level:

$$R_{i,t+1} = \alpha + \gamma_{i,t} \times X_{i,n,t-1} + \gamma_{n} \times X_{i,n,t-1} + + Year_{t} + \epsilon_{i,t+1}, \quad (27)$$

where $R_{i,t+1}$ is firm $i$’s annual stock return from July of year $t$ to June of year $t + 1$, $\beta_{i,t}^{KML}$ is a firm’s exposure to technology shock at the end of June of year $t$, $X_{i,n,t-1}$ are firm-level control variables at the end of year $t - 1$, and $Year_{t}$ is year fixed effect.

Table VII presents the results of estimating the panel regression (27). The specification in column (1) includes only a constant and $\beta^{KML}$. The estimated coefficient is negative and strongly significant. The coefficient implies an average return differential of -8.71% per year between firms with high and low $\beta^{KML}$. Including the year fixed effect, column (2), leads to a lower coefficient that implies a return premium of -3.64%. Columns (3)-(10) show results for regressions that include $\beta^{KML}$, year fixed effect and one of the control variables $X_{i,n,t}$. Each of these control variables has only a negligible impact on the estimated coefficient of $\beta^{KML}$. The coefficients are negative and significant across the specifications with different control variables. The implied return difference between firms with high and low $\beta^{KML}$ ranges from -3.29% to -4.62% per year. The regression in the last column controls jointly for all variables $X_{i,n,t}$ and the year fixed effect. The estimated coefficient of $\beta^{KML}$ remains negative and statistically significant. The slightly higher magnitude

---

39 The results are also very similar when the stocks are sorted into portfolios based on $\beta^{KML}$ that is estimated from multivariate rolling regressions including the size (SMB) and value (HML) factors of Fama and French (1993) as control variables (see table IA.16 in the appendix).

40 The control variables $X_{i,n,t-1}$ that are based on data from firms’ financial statements, i.e. book-to-market ratio, cashflow, financial leverage, price-to-cost margin, profitability, and size, are calculated from financial statements for fiscal year ending in year $t - 1$. This allows a lag of 6-18 months for the information to become publicly available. Market beta_{t-1} is estimated over the last 60 months ending in June of year $t$. Turnover is calculated over the calendar year $t - 1$.

41 I calculate the average return differential by multiplying the estimated coefficient of $\beta^{KML}$, -3.829, with the average difference in $\beta^{KML}$ between the 95th and 5th percentile, 2.275. This average difference in $\beta^{KML}$ is calculated as time-series average of contemporaneous interpercentile differences. The implied return premium for the average difference in $\beta^{KML}$ between the 75th and 25th percentile is -4.826%.
implies an annual return premium of -4.8%.

The estimated coefficients of $\beta^{KML}$ imply a similar return premium for firms’ exposure to technology shocks as the portfolio analysis described above. I show in online appendix table IA.17 that the estimation results are similar for the constituents of the S&P500. The coefficient of $\beta^{KML}$ is also robust to controlling for additional firm- and industry-level variables (see appendix tables IA.23 and IA.24).

The panel regressions assume a strictly linear relationship between stock returns and the cross-sectional return predictors. To control for a potentially non-linear relationship, I use conditional double sorts. Specifically, in the first step I sort stocks into three baskets based on the value of the control variable. In the second step, I sorts the stocks within each of these baskets again into three additional baskets according to the $\beta^{KML}$. This creates a total of 9 baskets. I then create three portfolios by pooling all stocks in the $\beta^{KML}$-based baskets with the same rank. This procedure creates portfolios sorted on $\beta^{KML}$ that are relatively independent of the return predictors used in the first step.

Table VIII reports the average value-weighted portfolio returns. I first report the average portfolio returns for unconditional sorting on $\beta^{KML}$, column (1). The average return differential based on unconditional sorting into three portfolios is -6.6% per year. Column (2) shows results for $\beta^{KML}$-sorted portfolios conditional on the book-to-market ratio. The portfolio with the low $\beta^{KML}$ stocks has the highest average return of 10.83% per year. The average return decreases monotonically across the remaining two portfolios. The conditional High-Low $\beta^{KML}$ portfolio earns a statistically and economically significant return premium of -5.23% per year. This return premium is relatively independent of the differences in firms’ book-to-market ratio. Columns (3)-(9) show that conditioning the portfolio sorts on other cross-sectional return predictors provides very similar results. The average portfolio returns decrease across the portfolios. The premium for the High-Low $\beta^{KML}$ portfolio ranges between -4.21% and -5.43% per year and is statistically significant and economically large. Results based on the constituents of S&P500 are very similar (see appendix table IA.18). The return premium is also robust to conditioning on other firm- and industry-level variables (see appendix table IA.25 and IA.26). For a comparison, the last column shows the premium for the book-to-market ratio conditional on firms’ size. The conditional value premium is 2.15% but not statistically significant.

The portfolio return analysis, panel regressions and conditional double sorts imply similar return premium for firms’ exposure to technology shocks. The latter two methods show that the return premium is not driven by linear or non-linear relationship with well-known cross-sectional return predictors. Negative return premium for technology shocks embodied in capital has been studied in several papers, e.g., Papanikolaou (2011); Kogan and Papanikolaou (2013, 2014). These papers

\[ \text{In an alternative approach, I first calculate time-series of value-weighted portfolio returns for each of the nine conditionally-sorted portfolios. I then create three portfolios by calculating a simple average across the } \beta^{KML}\text{-sorted portfolios with the same rank. The results based on this approach are very similar.} \]
focus primarily on the value-growth dimension and the negative premium is associated with firms that have large growth opportunities as they outperform during technology shocks. This mechanism is, to some extent, observable in the fifth portfolio. This portfolio earns negative alpha return with respect to CAPM in panel C of table VI. This return premium decreases in panel D as part of it is accounted for by the portfolio’s negative loading on the value factor HML (i.e., positive loading on growth factor). The majority of the premium in this study comes, however, from stocks that underperform during technology shocks and thereby earn higher expected return. This is apparent from the first four portfolios. These portfolios have negative exposure to technology shocks (see table IV) and the first three of them earn positive alpha return (see table VI). As these portfolios do not have any exposure to value/growth (HML) factor, they provide new and independent evidence of a return premium for technology shocks embodied in capital goods that complements the evidence in previous studies.

B. Time Variation and Predictability of the Return Premium

In this section, I examine whether the return premium varies over time and is predictable. As mentioned above, technology shocks are an important source of labor-income and job-displacement risk and the I-shock measure predicts higher moments of individual income growth distribution. Hence the I-shock measure can be considered a state variable for households’ marginal utility. This evidence gives rise to the consideration that a return premium of an asset with a strong exposure to technology shocks is predictable by this state variable.

I use the I-shock measure to forecast the return premium of the Low-High $\beta_{KML}$ portfolio. I focus on the Low-High $\beta_{KML}$ instead of High-Low $\beta_{KML}$ portfolio to facilitate the interpretation of the return premium. This portfolio has negative exposure to technology shocks and earns a positive return premium (i.e., it flips the negative sign shown in table VI). Specifically, I run forecasting regressions of the cumulative log return premium for the Low-High $\beta_{KML}$ portfolio, $\sum_{s=1}^{y} r_{t+s}$, over $y$ years, on the I-shock measure:

$$\sum_{s=1}^{y} r_{t+s} = a^{(y)} + b^{(y)} I_{\text{Shock}}^{t} + e_{t+y}^{(y)}. \tag{28}$$

Panel A of table IX reports the estimation results of the forecasting regression for the one-to five-year cumulative log return premium of the Low-High $\beta_{KML}$ portfolio. The estimated coefficients have the expected positive sign; a decrease in relative prices of capital goods - positive technology shock - increases the return premium. The estimated coefficients are marginally statistically significant for return horizons of two, three and four years. The magnitude of the coefficient is economically important. For example, a positive technology shock of one standard deviation increases the expected two-year return by 2.4%. Panel B shows the results of the forecasting re-
gressions that include additional forecasting variables. The estimated coefficient of the I-shock have similar magnitude and remain statistically significant for the same return horizons.

[Place Table IX about here]

Figure 7 plots the I-shock measure and the subsequent realized three-years cumulative log return premium of the Low-High $\beta^{KML}$ portfolio. The return premium varies over time together with the I-shock measure. Both time-series overlap relatively closely. Periods of substantial decreases in the relative prices of capital goods predict high return premium for the Low-High $\beta^{KML}$ portfolio.

[Place Figure 7 about here]

As discussed above, labor-income and job-displacement risk are high in states of large positive technology shocks. This evidence suggests that the time-varying return premium can be a compensation for this type of risk. Households will seek a return premium for assets that have negative exposure to states of high income risk. The time variation of the return premium between the states of high and low technology shocks supports this explanation.

The evidence and the characteristics of the return premium can encompass at least three economic mechanisms that broadly fit under the label of income risk. First, technology shocks increase job-displacement risk through automation and workers, who at the same time are investors, require a premium for this risk, which is reflected in stock prices of firms with strong exposure to these shocks. This can be seen as the most narrow interpretation of the model. For example, Autor and Dorn (2013) show that routine occupations are generally occupations with average income and it is possible that they include sufficient number of investors. Second, technology shock can increase not only job-displacement risk of workers but also place the business model or products of existing firms at risk. This makes also high level managers, whose income is tied to the firms’ performance, exposed to technology shocks even if they are not directly affected by automation as other workers. Small extensions of the model can enclose this mechanism. For example, assuming managers with a substantial stake in their firms and uncertainty over the success of automation where only a fraction of firms survives would allow for this interpretation. Governments can also seek to mitigate the high level of job-displacement risk faced by an increased number of workers through policies, e.g., income redistribution or wealth tax, that will also affect income of the part of the population that is not directly exposed to job loss through automation. Although this mechanism is not portrayed explicitly in my model, the two spouses under the roof of one household is a modeling shortcut that achieves this link. The relative importance of each of these effects is ultimately an empirical question that is beyond the scope of this paper.

C. Firms’ Responses to Technology Shocks

The evidence in earlier sections shows large differences in firms’ risk exposure to technology shocks. In this section, I investigate whether firms with different exposure to technology shocks

Electronic copy available at: https://ssrn.com/abstract=3293405
differ also in their employment, investment and financial performance when the relative prices of capital goods decrease. Costly employment and capital adjustments following technology shocks can affect firms’ financial performance and contribute to firms’ risk exposure. To explore this mechanism, I estimate panel regressions in the form:

$$\Delta y_{i,t+s} = constant + b_0 I_{Shock_t} + b_1 I_{\beta_{KML}^i} + b_2 I_{Shock_t} \times I_{\beta_{KML}^i} + \text{controls}_{i,t} + TFP_t + Trend_t + e_{i,t+s},$$

where $\Delta y_{i,t+s}$ is the firm $i$’s percentage change in employment, capital, capital-labor ratio, or percentage points change in return on equity between years $t$ and $t+1$. $I_{Shock_t}$ is the I-shock measure in year $t$, $I_{\beta_{KML}^i}$ is an index between 0 and 9 indicating the decile of cross-sectionally ranked firms’ exposure to technology shock, $\beta_{KML}^i$, and $I_{Shock_t} \times I_{\beta_{KML}^i}$ is their interaction term. $\text{Controls}_{i,t}$ is a set of firm-specific control variables consisting of firms’ capital, $K_{i,t}$, age, $Age_{i,t}$, book-to-market equity ratio, $B/M_{i,t}$, market capitalization, $Size_{i,t}$, firm fixed effects, and a lagged dependent variable at one-year horizon from $t-1$ to $t$. The regressions include TFP shock $TFP_t$ and deterministic trend $Trend_t$ as aggregate control variables.

Panel A of table X reports the results of estimating regression equation (29) for changes in employment and capital. The first column shows that a positive technology shock on average decreases firms’ employment. The coefficient of the I-shock measure is negative, statistically significant and economically large. The effect of the technology shock differs significantly across firms with different $\beta_{KML}^i$. The positive coefficient of the interaction term $I_{Shock_t} \times I_{\beta_{KML}^i}$ indicates that the effect is stronger for firms with negative exposure to technology shocks. In the next two columns, I split the sample in halves based on firms’ $\beta_{KML}^i$ and estimate the panel regression (29) without the interaction term. Firms in the first half have strongly negative exposure to technology shocks, while firms in the second half have only mild exposure that is much closer to zero (see table V). The results show that firms with strongly negative exposure decrease employment following a positive technology shock. At the same time, employment is on average constant in firms with mild exposure. The following three columns show that technology shocks increase firms’ capital. The effect is approximately equal for firms with strongly negative and mild exposure. This result indicates that lower quality-adjusted relative prices of capital goods lead to higher investment. It could be surprising that the estimated effect on firms’ capital do not differ strongly between firms with strongly negative and mild exposure to technology shocks. This seems to be due to the fact that Compustat reports only total capital which consists of property, plant and equipment. While plants are likely the dominant part of this measure for most of the companies, equipment, e.g., machines, software, computers, or robots, is more likely the type of capital that has the potential to replace human labor in routine tasks. Knesl (2018) differentiates between investment in equipment and investment in structures at the level of detailed manufacturing industries and shows that

\footnote{Using the index $I_{\beta_{KML}^i}$ indicating the decile of cross-sectionally ranked firms’ $\beta_{KML}^i$ instead of directly the firms’ exposure $\beta_{KML}^i$ helps minimize the noise in the dependent variable. See Kogan and Papanikolaou (2014) for a similar approach.}
technology shocks lead to significantly higher investment in equipment in manufacturing industries with highly displaceable labor while the effects on investment in structures do not differ much.

[Place Table X about here]  
The first three columns in panel B show that technology shocks increase firms’ capital-labor ratio. The effect is again stronger for firms with strongly negative exposure. As described earlier, firms with strongly negative exposure to technology shocks are generally firms with very high share of displaceable labor (see table V). The results indicate that these firms indeed adjust, potentially automate, their production processes by decreasing the number of employees and investing in capital when a technology shock occurs.

Panel B further reports the results for changes in return on equity. The last three columns show that lower relative prices of capital goods decrease firms’ return on equity. This effect is again larger for firms with strongly negative risk exposure. These firms experience decreases in return on equity almost twice as large as firms with mild exposure. The estimated coefficients are statistically significant and economically large. I also examine the effect on return on capital. The results are generally similar to those for return on equity and are provided in appendix table IA.28.

I repeat the analysis for different time horizons. I report the results for a time horizon of three years in appendix table IA.27. The results are qualitatively very similar. The estimated coefficients are generally larger as they refer to changes compounded over three years. These results indicate that the differential effects of technology shocks between firms with strong and mild risk exposure are not driven by potential lead-lag differences in firms’ responses.

The theoretical model presented earlier highlights the importance of competition for the economic mechanism how technology shocks affect firm value through costly technology adoption. I focus on this mechanism by solving the model for different degrees of elasticity of substitution for firm-specific goods, $\nu$, which governs the intensity of the within-industry competition. I plot the outcomes in figure 8. Panel A shows the equilibrium percentage of automating firms within the labor-intensive sector $\delta^*$. The dotted blue line shows the outcomes when the within-industry competition is low and firms earn high margin. The dashed red line depicts the case of medium competition and medium margin, and solid black line high competition and low margin. For a given magnitude of a technology shock, the equilibrium percentage of automating firms decreases with higher competition and lower margin. This is a result of two forces. First, higher competition increases the market-share stealing effect between automating and not-automating firms within the sector. This increases the incentive to automate. Hence automation can start occurring sooner in competitive industries than in industries with strong monopoly. Second, as the market-share stealing effect is stronger in more competitive industries, an individual firm’s profit is more sensitive to the number of other automating firms. The profit function of an automating firm decreases more abruptly as the number of other automating firms increases. The outcome in the figure shows that

[44]This obviously abstracts from potential market entrants who can be attracted by high margins and other important aspects.
conditionally on at least some firms optimally automating the second effect dominates and higher competition leads to a lower number of automating firms.

Panel B shows that the negative effects of technology shocks on income of firms with automation potential will be larger in highly competitive industries. Automating firms cannot retain higher rents in more competitive industries. Equivalently, the market-share stealing effect hurts the not-automating firms more strongly in more competitive industries. Firms go through costly automation to avoid this effect. At the same time, an increase in the percentage of automating firms erodes their rent abruptly. This effect is stronger in more competitive industries as mentioned earlier. The equilibrium impact on a firm’s profit is then relatively worse in a more competitive industry.

Panel C illustrates the effect of technology shocks on firms in capital-intensive sector. These firms are already capital-intensive and the element of strategic technology adoption is absent in this sector. Firms within this sector benefit equally from cheaper technology and technology shocks have positive effect on their profits proportional to the magnitude of the shock regardless of the degree of the within-industry competition.

I next investigate the importance of the within-industry competition empirically. I examine whether the effects of technology shocks on firms’ financial performance differ between firms in highly competitive and less competitive industries. To test this conjecture, I split the sample into two halves by the degree of competition and estimate the effect of technology shocks on firms with high and low automation potential within each half separately. I measure the degree of industry competition by the Herfindahl-Hirschman index (HHI) of sales at the level of SIC 3-digit industries.

Panel A of table XI reports the results for percentage point changes in the return on equity over one-year horizon. The first column is for firms with high automation potential in industries with low HHI indicating strong competition. The second column is for similar firms in less competitive industries. The estimated coefficient of the I-shock measure is more negative for firms in more competitive industries. To further show the differential effect I estimate a regression across all industries with an interaction term between the I-shock measure and an index indicating the tercile of the industry’s HHI. The interaction term is economically and statistically significant, supporting the results in the first two columns. The following three columns show the results for firms with low automation potential in competitive and less competitive industries. The estimated coefficient of the I-shock measure has again higher magnitude in more competitive industries although the coefficient is not statistically significant.

---

Imposing fixed investment cost in the amount of $\kappa$ on these firms additionally to their investment outlays wouldn’t change the nature of this result. As there is no strategic element embedded in the firm’s decision to invest, each firm in this sector will have positive investment irrespective of the occurrence of the technology shock and the action of other firms. Technology shock and the action of other firms then have impact only on the amount of investment.

Measuring the degree of competition which firms face within industries is empirically not a straightforward task due to various aspects of products, firms, markets and industries. Herfindahl-Hirschman index as a concentration-based measure does not speak to many of them directly or even indirectly. Syverson (2019) summarizes many aspects of measuring firms’ market power empirically. The use of the Herfindahl-Hirschman index is motivated by the availability of the necessary data for the whole time period and it should be understood that it provides only an imprecise measure of competition which firms face.
Panel B shows an equivalent set of results for percentage point changes in return on capital. The negative effects on return on capital are also more pronounced in more competitive industries. These results suggest that holding firms’ automation potential relatively constant, the within-industry competition increases the negative effect of technology shocks on firms’ financial performance. I report the results for horizon of three years in appendix table [IA.30]. The differences in the effects of technology shocks on firms’ financial performance between more competitive and less competitive industries are more pronounced at this longer horizon.[47] This suggests that competition plays an important role.

[Place Table XI about here]

The findings in this section document that firms with differential exposure to technology shocks have different employment and capital adjustment in years following a decrease in prices of capital goods, while financial performance is also affected. Firms with strongly negative exposure have generally high share of displaceable labor and tend to increase their capital-labor ratio after technology shocks. During this process their financial performance decreases. This evidence indicates that the risk exposure to technology shocks reflects firms’ financial underperformance after the shocks. Within-industry competition generally increases the magnitude of the negative effect on firms’ financial performance.

V. Conclusion

The potential of capital to substitute some types of labor and complement other plays a central role in economic models that study the effects of technological change. I find that firms’ potential to automate the production process is also an important determinant of firms’ exposure to technology shocks. Technology shocks embodied in capital are an important driver of stock returns with a differential impact over the cross section of stocks.

I show theoretically that the firms’ share of displaceable labor that can be automated by capital can increase firms’ riskiness in a competitive environment. Firms in industries with high displaceable labor share have negative exposure to technology shocks that facilitate automation. Automation becomes a costly necessity for firms to stay competitive as competition erodes potential rents from technological improvements for firms and passes them to the consumers in form of lower product prices. This result is supported by empirical evidence.

I show empirically that firms with high share of displaceable labor have very strong and negative exposure to technology shocks. I document that a macroeconomic measure of technology shocks based on prices of capital goods can be successfully approximated by stock returns of a zero-cost portfolio based on firms’ share of displaceable labor and this portfolios has captured all major technology shocks over the last four decades. I further show that firms exposure to technology

[47] Estimates of regressions weighted by firms’ sales are reported in appendix table [IA.31] and are similar in sign and magnitudes.
shocks that facilitate automation earn a robust and time-varying return premium that can be empirically and theoretically rationalized as a compensation for households’ job-displacement and labor-income risk. The exposure to technology shocks is associated with firms’ adjustment of the capital-labor ratio and underperformance after a decrease in relative prices of capital goods consistent with the model prediction.

My model abstracts from other interesting economic aspects such as market entry, differential ability to adopt new technology or operating leverage, which are certainly relevant in some real world scenarios and worth exploring both empirically and theoretically. Future research can also focus on a multiperiod fully dynamic setting with potentially endogenous arrival of technological improvements. Such model can deliver richer implications for asset prices as well as implications for differential growth between heterogeneous industries. Factors that determine ex-post winners of technological transformation among firms are of interest as well and can speak to changes in market power and evolution of firm and industry size.
Appendix A. Equilibrium and Market Clearing Conditions

The CES aggregator technology at the sector level implies an optimal demand functions for the firm-specific goods of the form:

\[ Y_{f,s,t} = \left( \frac{P_{f,s,t}}{P_{s,t}} \right)^{-\nu} Y_{s,t} \quad \text{and} \quad Y_{f,s,t} = \left( \frac{P_{k,f,s,t}}{P_{s,t}} \right)^{-\nu} Y_{s,t} \quad \text{for} \quad s = 1, 2 \quad \text{and} \quad t = 1, 2 \quad (A1) \]

The CES aggregator technology at the aggregate level implies an optimal demand function for the sector-specific goods of the form:

\[ Y_{s,t} = \left( \frac{P_{s,t}}{P_{A,t}} \right)^{-\rho} Y_{A,t} \quad (A2) \]

Market clearing condition for the aggregate good is defined as

\[ \sum_{h=1}^{N_h} c_{h,t} = Y_{A,t} \quad (A3) \]

Market clearing on the labor markets is defined as:

\[ L_{l,1,1} = \sum_{h=1}^{N_h} L_{h,1,1} \]

\[ L_{l,1,2} + L_{k,1,2} = \sum_{h=1}^{N_h} L_{h,1,2} \quad (A4) \]

\[ L_{k,1,t} = \sum_{h=1}^{N_h} L_{h,2,t} \quad \text{for} \quad t = 1, 2 \]

where the \( L_{l,s,t} \) is labor used directly in goods production in sector \( s \) and \( L_{k,s,t} \) is labor used in production of capital in sector \( s \). The market clearing on the capital investment market is:

\[ \sum_{f=1}^{N} K_{f,1,2} \mathbb{1} \{ \text{Automated} = \text{Yes} \} = K_{1,t}^\alpha \quad (A5) \]

\[ \sum_{f=1}^{N} K_{f,2,t} = K_{2,t}^\alpha \quad \text{for} \quad t = 1, 2. \]

Appendix B. The O*NET Database

The O*NET database provides a comprehensive set of characteristics describing occupations in a number of dimensions such as workers’ abilities, skills, knowledge and experience, work values, work styles, work activities, etc. The O*NET collects the underlying data in a two-stage design. First, O*NET selects a statistically random sample of businesses that are expected to employ targeted occupations. Second, it selects a random sample of workers in the targeted occupations.
within those businesses and collects the data by surveying the job incumbents using questionnaires. Additional variables such as variables describing skills and abilities are developed from the workers’ responses by occupational analysts. O*NET continuously updates the occupational characteristics by ongoing surveys and provides updated occupational characteristics in new database releases quarterly/semi-annually starting from 2003. This procedure allows to track the changes in occupational characteristics. The first releases of the O*NET database before 2003, however, are based on the data from Dictionary of Occupational Titles (DOT), which is a predecessor of O*NET. The underlying data in DOT refers to years 1991 (revised 4th edition) and 1977 (4th edition). The number of occupations in the O*NET database releases varies between 812 and 1122 occupations depending on the occupational classification used in each database release. The occupations are currently classified by the 2010 O*NET - Standard Occupational Classification (O*NET SOC) that is a refined classification based on 2010 Standard Occupational Classification (SOC).

Appendix C. Validity and Robustness of the RTI Measure

The construction of the RTI measure involves some degree of subjectivity in selecting the underlying descriptors as well as in the aggregation of the task inputs into one number expressing the routine task intensity. To address the potential concerns stemming from the freedom of selecting the underlying descriptors, I constructed alternative RTI measures from subsets and extended sets of descriptors and found that alternative measures identify routine and non-routine occupations in a very similar way. An aggregation of the underlying task inputs without logarithmic transformation as in formula also generates very comparable RTI measure. I also compare my RTI measure with the original RTI measure from . When matched to the common occupational classification, the measures have strong positive correlations across the occupations. Routine intensive occupations identified by each of these measures overlap and the overlap is also strong for non-routine occupations. The fact that these measures are constructed from different data sources and using different occupational characteristics but still succeed to identify the occupational routine task intensity in a very similar way increases the validity of these measures. Despite these validity and robustness checks, the use of the RTI measure still requires caution. First the underlying data can still be subject to some measurement errors and the selected descriptors may not necessarily describe all dimensions of routine intensity or automation potential of a given occupation. Second the RTI measure is defined only up to the occupational level and hence omits any variation in the routine task intensity across workers in the same occupation or of the same occupation across different firms. Given these concerns, the RTI measure has to be considered as an imprecise measure of the routine tasks and automation potential. Second, the given specification of the RTI measure is still time- and technology-dependent. Although, I use multiple data sources that update the occu-

48 The previous releases of the O*NET database are based on previous versions of O*NET-SOC, namely 2000, 2006, and 2009. The first release of the O*NET database in 1998 uses O*NET 98 OU classification that is based on the Occupational Employment Statistics classification (OES classification).

49 Discusses the challenges of measuring task inputs in more detail.
pational characteristics over time, the choice of the underlying descriptors reflects the current and past state of the technology. For instance, 'Operating vehicles, mechanized devices, or equipment' is used as a descriptor of non-routine manual task input. Using this measure, occupations such as bus, truck, and taxi drivers or commercial pilots are ranked as non-routine which reflects the state of the technology in most of the 20th century. The advances in technology, however, change the character of these occupations towards more routine intensive and potentially automatable. For example, various version of autopilots are widely used in commercial airplanes and their capabilities to assist during different phases of the flight have been constantly increasing. Similarly, a number of tasks involved in driving a car or truck, such as manually changing the gears or navigation, have been automated or significantly facilitated. Currently a number of companies both within and outside of car manufacturing are developing and testing systems for autonomous/automated vehicles. Given the ongoing changes in the available technology, this descriptor, 'Operating vehicles, mechanized devices, or equipment', may be re-classified to measure routine manual input in near future.

I match the RTI measured at the occupational level to firm-level observations by the OES conducted by Bureau of Labor Statistics. OES provides detailed tables of occupational composition of the labor force at a detailed industry level starting from 1988. The industries are classified at SIC 3-digit or NAICS 4-digit level across the whole U.S. economy. The number of industries ranges between 290 and 378. I extrapolate the occupational composition from the first OES releases to the years before 1988 to extend my sample to 1970. To translate the RTI measure from occupational level to industry level, I calculate for each industry the percentage of employees employed in routine intensive occupations. I define routine intensive occupations as occupations above the top employment-weighted tercile of occupations ranked by the RTI score in a given year. I report the exact match of the underlying OES file and the corresponding release of the O*NET database in the online appendix table IA.20. I transform the RTI from industry to firm level by imposing the percentage of employees in routine occupations in a given industry to all firms in that industry. Since the main focus of this paper is on the between-industry variation, the omission of the intra-industry variation in the RTI is not a limitation. Moreover, I show in the text that there is a strong relationship between labor-intensity and routine task intensity.

To validate the AP measure, I examine whether it can predict future automation. Automation, generally, refers to the substitution of machines or equipment for human workers in performing specific tasks. This can be reflected in various adjustments such as higher use of machines, reduction of employment and/or changes in the use of technology by specific occupations. Table IA.8 in online appendix shows that industry’s share of routine labor predicts the use of information and communication equipment (ICT) per worker over the following two decades. This relationship is especially strong for manufacturing industries and is robust to other factors such as offshorability and import penetration. I next examine whether the RTI also predicts the use of technology within

50 I report the exact number of industries in each OES release in online appendix, table IA.19
51 The results in the subsequent sections are very similar if I use different thresholds such as 70-th percentile or 80-th percentile.
occupations. For each occupation, I calculate a technology-use index measuring the use of various forms of technology such as computers and electronics and the importance of technology-relevant skills such as programming or controlling machines. I report the full set of the underlying variables in online appendix table [A.6]. Table [A.9] in online appendix shows that occupational routine task intensity predicts the use of technology at occupational level. Occupations with relatively higher RTI score experienced relatively higher increase in the technology-use index in the following years. These two results indicate that the AP measure and its component, the RTI measure, indeed predict automation at industry and occupational level, respectively.

Appendix D. Filtering the Stock Return Data

The sample consists of common stocks listed at the NYSE, NASDAQ, and AMEX. I exclude financials SIC 6000-6799, utilities SIC 4900-4999, and public sector companies SIC ≥ 9000. To avoid the results to be driven by small and micro-cap firms, I exclude the bottom 20% of firms ranked by market capitalization. I also exclude the bottom 10% of firms ranked by the share price. The results are similar when firms with share price below 2 dollars are excluded. I further exclude firms in the bottom 5% by trading volume. Results are similar when more restrictive percentiles are applied. I further exclude firms with less than 500 employees or total net property, plant and equipment less than 5 millions. Estimation of firm’s betas requires the firm to have monthly data over at least last 30 months. The sample of S&P500 firms consists of the continuously updated index constituents. I also exclude financials and utilities.

Appendix E. Measuring the Technology Shocks Embodied in Capital, Details

I formally derive the validity of the I-shock measure in a simple two-sector model from Cummins and Violante (2002). Final goods producers competitively produce final goods $x_t$ at price $p_c^t$. The final goods can be either consumed or used as an input for production of capital goods. The capital goods sector can produce $i_t$ efficiency units from $x_t$ units of consumption goods according to production function $i_t = q_t x_t$. $q_t$ captures the level of technology in the capital goods sector. Prices in the capital goods sector are set competitively so that $p_i^t i_t = p_c^t x_t$. Combining this result with the production function leads to $p_i^t / p_c^t = 1/q_t$ and hence $\Delta q_t = \Delta p_i^t - \Delta p_c^t$. Accordingly, the changes in the prices of capital goods relative to consumption goods measure the investment specific technology shock embodied in capital, $q_t$. Based on this model, I construct the measures of the technology shock by subtracting the annual log changes in the quality-adjusted prices of capital.

---

52 Other studies also provide supportive evidence. For instance, a companion paper Knesl (2018) shows that manufacturing industries with a high share of routine labor substitute equipment capital for human workers following technology shocks. Autor and Dorn (2013) document a differential reduction of employment of routine occupations in commuting zone with originally high share of routine labor. Spitz-Oener (2006) documents a differential increase in requirements for complex skills in rapidly computerizing occupations.
goods from the log changes in prices of consumption goods. Accordingly, an increase in the I-shock measure indicates a positive technology shock embodied in capital.

The prices of the capital goods are from the price index of private fixed investment in nonresidential equipment provided by the U.S. Bureau of Economic Analysis. This price index is a composite of price indexes of 25 different types of equipment that are broadly categorized as information processing equipment, industrial equipment, transportation equipment, and other equipment. I measure the aggregate prices by the BEA’s price index of personal consumption expenditures for nondurable goods. The sampling frequency of both time series is annual. I use the data from 1970 to 2015. To account for a possible bias due to the lack of quality adjustment in the price indexes of capital goods, I use the underlying data from Cummins and Violante (2002) and extrapolate the quality adjustment until 2015. The data in Cummins and Violante (2002) directly accounts for the quality changes in the 24 types of equipment that comprise the aggregate price index of capital goods. The quality adjustment is based on the original data from Gordon (1990). To construct the I-shock measure, I subtract the log change in the quality-adjusted prices of capital goods from the log change in prices of nondurable consumption goods. I also calculate an alternative measure without using the quality adjustment from Cummins and Violante (2002). This measure relies completely on the quality adjustment in the underlying price indexes from BEA. The results in this paper are very similar when I use the alternative measure. The time-series variation of both measures is very similar. The major difference between the quality-adjusted and the alternative measure is the long-term average. The average is higher for the quality-adjusted measure as it reflects the improvements in quality of the capital goods over time.

Figure 2. Three Types of Sector Equilibria. This figure plots the relationship between the prices of goods (panel A), demand for goods (panel B), and dividends (panel C) of labor-based and automated firms within the sector $s = 1$ and the percentage of automated firms in this sector, $\delta$. Plots in the first column show a state of no shock. The parameter $A_2$ is chosen so that the good prices of each type of firm are same when no firm automates ($\delta^* = 0$). Plots in the middle column show a situation with an incremental technology shock when a percentage of firms ($0 < \delta^* < 1$) automates. Plots on the right-hand side show a situation of large disruptive technology shocks when all firms in the sector automate despite automation cost $\kappa$, ($\delta^* = 1$). The black horizontal line depicts the original dividend level. The model parameters are: $\rho = 4$, $\nu = 14.2$, $\alpha = 0.965$, $\chi = 1$, $\theta = 2$, $N = 1000$, $N_h = 100$, $A^{Low} = 0.89$, $A^{High} = 1.0$, $1.05$, $\beta = 0.85$, $\gamma = 32.5$, $\epsilon = 0.32$, $p_H = 0.10$, $p_e = 0.5$, and $\kappa = 8 \times 10^{-5}$. The demand for firms’ goods and firms’ dividends are scaled by a factor 1000.
Figure 3. Technological Shocks, Equilibrium Automation, and Profits. This figure plots the equilibrium relationship between the magnitude of the technology shock $A_t$ and percentage of firms that automate within the sector 1 (panel A), the dividends of firms in sector 1 (panel B) and the dividends of firms in sector 2 (panel C). Model parameters are stated in the description of figure 2. Dividends are scaled by a factor 1000.

Figure 4. Firms' Exposure to Technological Shock and Expected Returns. This figure plots the relationship between the magnitude of the technology shocks and firms' exposure (panel A), the relationship between the magnitude of the technology shock and expected stock returns (panel B), and the differences in expected stock returns between firms in sector 1 and sector 2 (panel C). Model parameters are stated in the description of figure 2.
Figure 5. Idiosyncratic Labor Productivity $\epsilon$ and the Risk Premium for Technological Shocks. This figure plots the risk premium for technology shocks $E[R^t] - R_f$ as a function of the idiosyncratic labor productivity risk $\epsilon$. $R^t$ is a return on an asset that has $\beta = 1$ to technology shock $A_2$. The magnitude of the technology shock $A^{High}_{2}$ is chosen so that all firms in sector $s = 1$ automate ($\delta^*$). Model parameters are stated in the description of figure 2.
Figure 6. Technological Shocks (I-shock) and Low AP minus High AP Firms. This figure plots the I-shock measure (dashed blue line) and the annual return of the zero-cost (KML) portfolio (solid red line). The zero-cost portfolio has a long position in firms with low share of displaceable labor, i.e. the bottom quintile of firms ranked by the AP measure, and a short position in firms with high share of displaceable labor, i.e. the top quintile. The portfolio returns within the short and long position of the KML portfolio are value weighted. The KML portfolio in this figure consists of stocks from S&P500 except for financial and utilities firms. Both time-series are plotted at annual frequency and are normalized to mean zero and standard deviation of one. The sample period is from 1970 to 2015.
Figure 7. The I-shock Measure and Following 3-Year Cumulative Return of the Low-High $\beta^{KML}$ Portfolio. This figure plots the I-shock measure (dashed blue line) and the subsequent realized three-year cumulative log return of the zero-cost Low-High $\beta^{KML}$ portfolio (solid red line). The zero-cost portfolio has a long position in stocks with low $\beta^{KML}$ and short position in stocks with high $\beta^{KML}$. The portfolio returns within the short and long position are value-weighted. The portfolio is rebalanced annually at the end of June. Both time-series are plotted at annual frequency and are normalized to mean zero and standard deviation of one. The sample period is from 1970 to 2015.
Figure 8. Technology Shocks, Equilibrium Automation, and Profits at Different Margins.
This figure plots the equilibrium relationship between the magnitude of the technology shock $A_t$ and percentage of firms that automate within the sector 1 (panel A), the dividends of firms in sector 1 (panel B) and the dividends of firms in sector 2 (panel C) at three different levels of profit margins (high, medium, and low). High profit margins are defined by low elasticity of substitution $\nu = 10.0$, medium profit margins by $\nu = 14.2$ and low profit margins by $\nu = 20$. Other model parameters are stated in the description of figure 2. Dividends and the magnitude of the technology shock $A_t$ are normalized to allow comparison between model solutions at different parameter values.
Table I
Summary Statistics and Variance Decomposition of the AP measure

This table reports the summary statistics of the AP measure and its main components, $\ln \left( \frac{K}{L} \right)$ and $\frac{L_{\text{routine}}}{L_{\text{total}}}$. (-)AP denotes $\ln \left( \frac{K}{L_{\text{routine}}} \right)$ to avoid negative numbers and facilitate readability. The reported results are time-series averages of cross-sectional statistics. Panel A shows the summary statistics at the firm level and panel B at the industry level. Panel C reports the variance decomposition of the 1/AP measure and its components into within- and between-industry variance. The number in panel C denote the percentage of total variance. By construction, $\frac{L_{\text{routine}}}{L_{\text{total}}}$ has 100% variance at industry level. Industries are defined at SIC 1987 3-digit and NAICS 2002 4-digit level.

Table II
Technology Shocks and Income Growth

This table reports the results of regressing contemporaneous and future growth of income per capita, cross-sectional average of income growth and change in moments of cross-sectional income growth distribution on the I-shock measure and TFP shock. The regression is of the form
\[ \frac{1}{K+1} \sum_{k=0}^{K} y_{t+k} - y_{t+k-1} = \alpha + \gamma_{I\text{shock}} \times I_{\text{shock}} + \gamma_{T\text{FP}} \times T\text{FP} + \epsilon_{t+k}, \]
for time horizons \( K = 0, 1, \) and \( 2. \) \( y_{t+k} - y_{t+k-1} \) is the log growth rate in average income per capita in the first three columns and cross-sectional average of personal income growth in the last three columns of panel A and a change in the standard deviation and skewness of cross-sectional personal income growth as labeled in panel B. \( I_{\text{shock}} \) is the I-shock measure representing the change in quality-adjusted relative prices of capital goods between \( t-1 \) and \( t. \) \( T\text{FP} \) is the change in aggregate productivity between \( t-1 \) and \( t. \) The regressions are estimated at annual frequency. The time period in the first three columns of panel A is from 1975 to 2015 and from 1978 to 2010 in the remaining part. *** Significant at the 1 percent level. ** Significant at the 5 percent level. * Significant at the 10 percent level. Source: Income per capita: U.S. Bureau of Economic Analysis; Moments of income growth distribution: Guvenen et al. (2014).

Table III

Correlation between the I-shock Measure and the Long-Short (KML) Portfolios Based on the between- and within-industry Automation Potential

This table reports the correlation coefficients between the I-shock measure and the long-short portfolio (KML) constructed by the AP measure based on within or between industry variations. The long-short portfolios in the 'Between' row are constructed by ranking industries by the industry-level average share of displaceable labor, AP. The long position consists of industries in the bottom quintile ranked by the AP measure and the short position of industries in the top quintile. The long-short portfolios in the 'Within' row are constructed by ranking individual firms by firms' deviation from the industry average share of displaceable labor. The long position consists of firms in the bottom quintile ranked deviation from industry’s average AP and the short position of firms in the top quintile. Industries are defined at SIC 4-digit level in column 1, SIC 3-digit level in column 2, NAICS 6-digit level in column 3, and NAICS 5-digit level in column 4.

Table IV
Exposure of Portfolio Returns to Technological Shocks (I-shocks)

This table reports the results from regressing portfolio annual excess returns on a constant, the I-shock measure and return factors. Regressions in panel A include a constant and the I-shock measure. The aggregate market return (CRSP value-weighted index) is added to the regressions in panel B, and the size (SMB) and value (HML) factors of Fama and French (1993) are added to the regressions in panel C. Stocks are assigned to one of five portfolios based on the share of displaceable labor, AP. Portfolios are rebalanced annually at the end of June. Portfolio returns are value-weighted. The sample period is from 1970 to 2015. Newey and West (1987) standard errors are in parentheses. *** Significant at the 1 percent level. ** Significant at the 5 percent level. * Significant at the 10 percent level.

This table reports the results from regressing portfolio annual excess returns on a constant and the I-shock measure in panel A and time-series averages of additional characteristics across the stocks within each portfolio in panel B. Stocks are assigned to one of five to portfolios based on their exposure to the KML portfolio, $\beta_{KML}^i$. Portfolios are rebalanced annually at the end of June. Portfolio returns are value-weighted. Newey and West (1987) standard errors are in parentheses. (-)AP is the negative of firm’s displaceable labor share measured by $(-1) \times \ln \left( \frac{L_{\text{routine}}}{K} \right)$, BM is the book-to-market ratio, $\beta_{\text{market}}$ is the regression coefficient of market excess return from rolling time-series regressions of firm excess return onto market excess return and a constant, CF denotes cash flow, Lev denotes financial leverage, PCM denotes the price-to-cost margin, Profitability is the ratio of sales minus cost of goods sold, interest expenses, and selling, general, and administrative expenses to book equity, Size is the natural logarithm of the market capitalization in thousands, and Turnover is the fraction of shares traded to the total shares outstanding. The sample period is from 1975 to 2015. *** Significant at the 1 percent level. ** Significant at the 5 percent level. * Significant at the 10 percent level.

Table VI
Mean Portfolio Returns and Alphas of Portfolios Sorted on $\beta^{KML}$

This table reports the time-series averages of value-weighted portfolio excess returns in panel A, equally-weighted portfolio excess returns in panel B, results of regressing monthly value-weighted portfolio excess returns on a constant and market excess return in panel C and results of regressing monthly value-weighted portfolio returns on a constant, market excess return, and the size (SMB) and value (HML) factors of Fama and French (1993) in panel D. Newey and West (1987) standard errors are reported in parentheses. Stocks are assigned to one of five portfolios based on their exposure to the KML portfolio, $\beta^{KML}$, is estimated from rolling regressions of stock’s monthly excess return on a constant and monthly return of the KML portfolio over the last 60 months. Portfolios are rebalanced annually at the end of June. The average excess returns and standard errors in panel A and B are annualized averages of monthly excess returns. The alpha estimates and their standard errors in panel C and D are annualized. The sample period is from 1975 to 2015. *** Significant at the 1 percent level. ** Significant at the 5 percent level. * Significant at the 10 percent level.

Table VII
Panel Regressions of Annual Stock Returns on $\beta^{KML}$ and Firm Characteristics

This table reports the results of regressing annual stock returns on a constant, $\beta^{KML}$, other stocks characteristics and year fixed effect as indicated. Standard errors are clustered at the firm level and reported in parentheses. $\beta^{KML}$ is estimated from rolling regressions of stock’s monthly excess return on a constant and monthly return of the KML portfolio over the last 60 months. BM is the book-to-market equity ratio, $\beta^{market}$ is the regression coefficient of market excess return from rolling time-series regression of firm excess return onto market excess return and a constant, CF denotes cash flow, Lev denotes financial leverage, PCM denotes the price-to-cost margin, Profitability is the ratio of sales minus cost of goods sold, interest expenses, and selling, general, and administrative expenses to book equity, Size is the natural logarithm of the market capitalization in thousands, and Turnover is the fraction of shares traded to the total shares outstanding. The sample period is from 1975 to 2015. *** Significant at the 1 percent level. ** Significant at the 5 percent level. * Significant at the 10 percent level.

Table VIII
Mean Portfolio Returns for Conditionally Double-Sorted Portfolios

This table reports the average excess returns for conditionally double-sorted portfolios. In the first step, I sort stocks into three baskets based on the control variable indicated in each column. In the second step, I sort stocks within each of these three baskets into three additional baskets based on $\beta^{KML}$ resulting in nine portfolios in total. I then create three portfolios by pooling the stocks in the $\beta^{KML}$-based baskets with the same rank. I report the annualized average value-weighted returns for portfolios with conditionally low-, medium-, and high-$\beta^{KML}$ stocks as well as for the High-Low $\beta^{KML}$ portfolio. Newey and West (1987) standard errors are in parentheses. $\beta^{KML}$ is estimated from rolling regressions of stock’s monthly excess return on a constant and monthly return of the KML portfolio over the last 60 months. BM is the book-to-market equity ratio, $\beta^{market}$ is the regression coefficient of market excess return from rolling time-series regression of firm excess return onto market excess return and a constant, CF denotes cash flow, Lev denotes financial leverage, PCM denotes the price-to-cost margin, Profitability is the ratio of sales minus cost of goods sold, interest expenses, and selling, general, and administrative expenses to book equity, Size is the natural logarithm of the market capitalization in thousands, and Turnover is the fraction of shares traded to the total shares outstanding. The first column shows average excess return for unconditional sorting based on $\beta^{KML}$. The last column reports average excess return for sorting on BM conditional on Size. The sample period is from 1975 to 2015. *** Significant at the 1 percent level. ** Significant at the 5 percent level. * Significant at the 10 percent level.

Table IX
Long-Horizon Predictability of the Return Premium

This table reports the results of forecasting regressions of the y-year cumulative annual log return premium of the Low-High $\beta^{KML}$ portfolio on the I-shock measure in panel A. Panel B shows the results of forecasting regressions that include also the aggregate economic growth (GDP), a proxy for the consumption-wealth ratio (cay) of [Letttau and Ludvigson (2001)], and the price-earnings ratio (CAPE P/E10) of [Campbell and Shiller (1988)]. The horizon of the cumulative log return is indicated in columns. Low-High $\beta^{KML}$ portfolio consists of a long position in stocks with low $\beta^{KML}$ and a short position in stocks with high $\beta^{KML}$. The portfolio is rebalanced annually at the end of June. The portfolio returns are value-weighted. [Newey and West (1987)] standard errors are reported in parentheses and [Hansen and Hodrick (1980)] standard errors in brackets. The sample period is from 1970 to 2015. *** Significant at the 1 percent level. ** Significant at the 5 percent level. * Significant at the 10 percent level. Source: The data for aggregate economic growth: U.S. Bureau of Economic Analysis; the proxy for the consumption-wealth ratio: Martin Lettau’s website; the price-earnings ratio: Robert Shiller’s website.

This table reports the results of regressing firm-level percentage changes in employment and capital in panel A and percentage changes in capital-labor ratio and percentage point changes in return on equity in Panel B, between years $t$ and $t+1$ on the I-shock measure in year $t$, $I_{shock_t}$, firm $i$’s exposure to technology shock in year $t$ measured by the deciles’ index, $I_{i,t}^{β_{KML}}$, of cross-sectionally ranked $β_{i,t}^{KML}$, and their interaction term, $I_{shock_t} \times I_{i,t}^{β_{KML}}$. The regressions include aggregate TFP shock, $TFP_t$, and deterministic trend, $Trend_t$, as aggregate control variables and firm $i$’s capital, $K_{i,t}$, age, $Age_{i,t}$, book-to-market equity ratio, $B/M_{i,t}$, market capitalization, $Size_{i,t}$, lagged dependent variable for one-year horizon $t-1$ to $t$, and firm fixed effects as firm-specific control variables. Columns $β_{KML} \leq$ median and $β_{KML} >$ median show results of the regressions without the interaction term estimated for firms with below and above median $β_{KML}$, respectively. Standard errors are clustered at SIC 4-digit industry level and reported in parentheses. The sample period is from 1975 to 2015. *** Significant at the 1 percent level. ** Significant at the 5 percent level. * Significant at the 10 percent level.

Table XI
Firms’ One-Year Response to Technology Shocks, Highly Competitive versus Less Competitive Industries

This table reports the results of regressing firm-level percentage point changes in the return on equity (panel A) and the return on capital (panel B) between years \( t \) and \( t + 1 \) on the I-shock measure in year \( t \), \( Ishock_t \). The regressions include aggregate TFP shock, \( TFP_t \), and deterministic trend, \( Trend_t \), as aggregate control variables and firm \( i \)'s automation potential, \( AP_{i,t} \), capital, \( K_{i,t} \), age, \( Age_{i,t} \), book-to-market equity ratio, \( B/M_{i,t} \), market capitalization, \( Size_{i,t} \), lagged dependent variable for one-year horizon \( t - 1 \) to \( t \), and firm fixed effects as firm-specific control variables. The regressions are estimated for firms with below and above median automation potential \( AP_{i,t} \) in industries with high and low competition as indicated. Industries with high and low competition are industries with below and above median Herfindahl-Hirschman index of sales at the SIC 3-digit industry level. Regressions in columns ‘All industries’ are estimated for firms with high and low AP across all industries with an interaction between the I-shock measure and an index indicating the tercile of industries ranked by the Herfindahl-Hirschman index. Standard errors are clustered at NAICS 6-digit industry level and reported in parentheses. The sample period is from 1975 to 2015. *** Significant at the 1 percent level. ** Significant at the 5 percent level. * Significant at the 10 percent level.
